surgical history, conditions of conception and sociodemographic characteristics. Maternal cigarette smoking was assessed by the number of cigarettes smoked per day at the time of conception. Information about the main sexual partner included: number of cigarettes smoked per day, educational level, socio-occupational class, and number of STDs during the past six months. Odds ratios (OR) and 95% confidence interval (CI) were used to describe the association between ectopic pregnancy and smoking.[9] Unconditional multiple logistic regression was performed to control for maternity hospital and to adjust for the confounding effects of other exposures.[10] The proportion of cases that can be attributed to cigarette smoking was assessed by the adjusted population attributable fraction calculated with a formula given by Walter,[11] and adapted for multivariate settings by Bruzzi, *et al.*[12]

Results

The main sociodemographic characteristics of cases and controls were similar except for age (Table 1).

A higher proportion of cases (40.1 percent) than controls (29.7 percent) were smokers at the time of conception (OR = 1.64, 95% CI: 1.15, 2.33). Furthermore, when smoking was analyzed as a categorical variable, we observed a clear dose gradient relationship between cigarette smoking and ectopic pregnancy (Table 2) (OR = 1.21 to 1.64, trend tendency $p < 0.05$). Variables adjusted for in the logistic regression model included: age, appendectomy, prior ectopic pregnancy, prior tubal surgery, prior spontaneous abortion, previous use of IUD, PID, induced conception cycle, use of IUD, combined contraceptive pill or progestative micropill at the time of conception. Adjustment slightly increased the crude estimates (Table 2). On the other hand, there was no association with partner's smoking (OR = 0.82, 95% CI: 0.58, 1.16). Since the adjusted OR of the ectopic pregnancy association with cigarette smoking was 1.68 and the prevalence of smoking among the controls was 0.30, the adjusted population attributable fraction in our population was 17 percent.

Discussion

We found an increased risk of ectopic pregnancy in women who were smokers at the time of conception. This association is supported by the dose-response relationship observed even after adjustment for identified confounding variables. Conversely, no such association was found with partner's smoking, an association not previously investigated. These results seem to eliminate possible masked behavioral confounding factors and strengthen the argument that cigarette smoking was a true direct risk factor of ectopic pregnancy.

Several potential sources of bias must be considered. Since cases and controls had similar demographic characteristics and since adjustment for the center was performed, selection bias is probably limited. However, recall bias which may have led to an overestimation of the risk, bias associated with the misclassification of the recent quitters (probably small according to Chow),[7] and the confounding effects of unidentified risk factors cannot be totally excluded.

Our findings are consistent with six previous epidemiological studies which collected information on maternal smoking habits.[3-8] Despite methodological differences, these studies all found a positive association. Chow, *et al*,[7] found a positive association between smoking at the time of conception and ectopic pregnancy (adjusted OR = 2.2), but failed to demonstrate a dose-response relationship. In the study of Handler, *et al*[8], the estimated relative risk associated with smoking rose from 1.4 for a woman smoking fewer than 10 cigarettes per day to 5.0 for 30 or more cigarettes per day. In that study, however, smoking was assessed during pregnancy. Because the pregnancies of the controls were longer, these women had greater possibility than cases to stop smoking during pregnancy and this may have led to an overestimation of the relative risk.

Alterations of tubal motility and ciliary function following injections of nicotine have been demonstrated.[13] Nicotine also delays blastocyst implantation and alters spacing of implantation sites[14] in animals. The possible role of low estrogen-levels is advocated by some authors.[15] Several findings support this hypothesis: women smokers have lower estrogen-levels than controls[16] and tubal contractions are clearly under estrogenic control.[17] Another explanation for the deleterious effect of smoking involves the reduced immunity in cigarette smokers.[18,19] The altered immunity may affect the tubal response to inflammation, resulting in an increased frequency of PID.[7] However, the association between smoking and PID has not yet been extensively explored in epidemiological studies.

Our observed population attributable fraction of nearly 20 percent indicates the public health importance of this association. If a factor is a causal agent of the disease, the reduction in the rate which would occur if exposure is prevented is equal to this proportion.[11]

In conclusion, our study provides a supplementary argument for the existence of a causal link between cigarette smoking and ectopic pregnancy. Smoking is widespread among women in many countries. In some cases, the prevalence among young women is ever increasing.[20,21] The

Effects of a Worksite Nonsmoking Policy: Evidence for Increased Cessation

Glorian Sorsensen, PhD, MPH, Nancy Rigotti, MD, Amy Rosen, PhD, John Pinney, and Ray Prible, MD

ABSTRACT

A random sample of employees was surveyed 20 months after a nonsmoking policy was implemented at the New England Telephone Company in 1986. Overall, 21 percent of respondents who were smoking at the time they heard about the policy had quit smoking; 42 percent of quitters said they stopped smoking because of the policy. Cessation was highest among those who reported less smoke in their work area, but was not related to participation in cessation programs. This study suggests that worksite nonsmoking policies may have favorable effects on smoking cessation. (*Am J Public Health* 1991; 81:202–204)

Introduction

As evidence of health risks associated with passive smoking has accumulated, more worksites have adopted policies that restrict smoking.[1] Studies evaluating these policies, largely in health care facilities, have reported that nonsmoking policies are generally well-received, improve air quality, and reduce cigarette consumption.[2-6] However, there is little evidence that nonsmoking policies stimulate smoking cessation, and the generalizability of these findings to other worksites is not known.

On July 1, 1985, the New England Telephone Company, which employed 27,374 persons at approximately 600 sites, announced a company-wide policy restricting smoking. Beginning September 1, 1985, smoking was banned in conference rooms and classrooms and restricted in cafeterias and lounges. On March 1, 1986, smoking was prohibited in all work areas, including individual offices. Smoking areas were designated in cafeterias, lounges, hallways, and restrooms. A full-time field manager was appointed for 18 months to facilitate the implementation and enforcement of the policy. Free onsite smoking cessation classes were offered. This study examines the effects of this smoking policy on employee smoking behavior and perceived air quality.

Methods

Employees were surveyed in November 1987. The self-administered anonymous survey was distributed through company mail to a stratified random sample of 1,599 employees, including 892 nonmanagers (4.3 percent of technicians, operators, and secretarial/clerical staff), 494 (7.7 percent) lower level managers, and 213 (49.9 percent) upper level managers. The overall response rate was 74.5 percent (N = 1,192): 65 percent among nonmanagers, 86 percent among lower level managers, and 84 percent among upper level managers (three responses to job category were missing). Analysis is limited to data from the 1,120 (94 percent) respondents employed when the policy was implemented.

Respondents were asked about their current smoking status and smoking status when they first became aware that the company had or would be establishing a policy about smoking. Quitters were defined as those who were smokers when they first became aware of the policy and were not smoking when surveyed. Smokers included those smoking cigarettes, pipes, or cigars. As an indicator of compliance, respondents were asked about air quality in work and nonwork areas.

Relationships among these variables were examined using chi square analysis. The results are reported by job category wherever significant differences by job status are found. Multiple logistic regression was used to identify predictors of smoking status.[7] Analyses were conducted using the software program SYSTAT.[8]

Results

Characteristics of the sample are presented in Table 1. Overall, 79 (21 percent) of the 375 respondents who were smokers when they first became aware of the policy said they were not smoking by the time of the survey 20 months later, including 15 percent of nonmanagers, 25 percent of lower level managers, and 32 percent of upper level managers (chi square = 8.6, p < .01). Omitting short term quitters (N = 13), 18 percent had quit for at least three months. Differences in smoking status by job category are not explained by age or

18–29	8.0	4.4	1.1
30–39	36.1	30.0	12.0
40–49	31.2	37.1	39.0
50+	24.7	28.5	42.9
Smoking Status When Respondent First Heard About the Policy	(n = 528)	(n = 411)	(n = 177)
Current Smoker	33.7	34.8	29.9
Former Smoker	30.7	33.8	42.4
Never Smoker	35.6	31.4	27.7
Present Smoking Status	(n = 528)	(n = 411)	(n = 177)
Current Smoker	29.7	27.3	20.9
Former Smoker	35.0	42.1	52.4
Never Smoker	35.2	30.7	27.1

Note: A total of 79 persons who were smoking when they first heard about the policy were not smoking when the survey was administered. Also, eight who reported former smoking and three who reported never smoking when they heard about the policy reported current smoking at the time of the survey.

sex, based on logistic regression analyses. Results of a multiple logistic regression analysis indicate that smoking cessation was more common among those reporting less smoke in work and nonwork areas (Table 2).

The policy was effective in reducing reported exposure to smoke in work areas but not in nonwork areas (Table 3). These results varied significantly by smoking status but not by job category.

Employees classified as smokers were asked: "Which of the following best describes the effect the company's policy about smoking at work has had on your smoking?" Of the 375 smokers, 32 (9 percent) reported that they quit smoking due to the policy, including 20 percent of upper level managers, 9 percent of lower level managers, and 6 percent of nonmanagers. This represents 42 percent of those who quit. In addition, 113 of 375 (32 percent) said that they reduced the number of cigarettes smoked as a result of the policy, including 36 percent of upper level managers, 34 percent of lower level managers, and 29 percent of nonmanagers.

Overall, 38 percent of respondents classified as smokers received some kind of cessation-related assistance. Smokers seeking help were no more likely to quit than those not seeking help (21 percent vs 20 percent). This result did not differ significantly by job category.

TABLE 2—Logistic Regression: Smoking Cessation,[1] with Independent Variables

Discussion

A major finding of this study was the overall quit rate of 21 percent over 20 months which is markedly higher than the expected population quit rate of 2 to 5 percent per year.[9,10] In addition, 42 percent of quitters said their cessation was a direct effect of the policy. Cessation was associated with working in areas of good policy compliance, as measured by perceived air quality, but not with participating in cessation classes.

The strengths of this study include data collection from a random sample of employees and retrospective cohort data on cessation. The response rate to the survey was high (75 percent) although it was higher among managers than nonmanagers. Limitations of the study include retrospectively collected data, which risks recall bias. However, a recent study reported 87 percent agreement between recall of smoking status 20 years ago and longitudinal records.[11] Assessment of smoking cessation was based on self-report, but anonymity of responses gave little motive to distort answers. Differing employee turnover rates between smokers and nonsmokers may have inflated cessation rates; however, only 1 percent of managers surveyed knew of any employee who had left the company due to the policy, and the smoking rate of new hires was higher than in established employees. Finally, there was no comparison company to control for secular trends and our results are compared only with reports from population-wide data.

These findings differ from earlier reports from studies in health care settings, which found no relationship between smoking policies and cessation. Findings from health care settings may not apply to other settings; smokers in health care settings may be more aware of the dangers of smoking and consist of a hard core group more resistant to change. These findings suggest that a well implemented worksite smoking policy, which is fully supported by management and accompanied by cessation classes, may be followed by apparent increases in smoking cessation by employees. ☐

Are People More Health Conscious? A Longitudinal Study of One Community

Minoo Niknian, PhD, R. Craig Lefebvre, PhD, and Richard A. Carleton, MD

ABSTRACT

Secular changes in cardiovascular health awareness, knowledge and behavior were observed in four biennial cross-sectional surveys and a cohort survey in a New England community. These changes are not related to more health promotion activities in the social milieu of respondents, but are more likely due to national mass media health campaigns, the effects of which may influence outcomes of community-based cardiovascular disease prevention studies. (*Am J Public Health* 1991; 81:203–205)

Introduction

Communication campaigns designed with the objective of improving the health status of a target population have become more prevalent in the past two decades.[1-8] Many of these campaigns have been based on the assumption that people will behave in prescribed ways given sufficient information and motivation to support such decisions. An understanding of how these national campaigns are currently affecting awareness, knowledge and behavior related to cardiovascular disease (CVD) and its risk factors is important for studies that will examine risk factor changes and morbidity/mortality in study populations.

The setting for this work is the Pawtucket Heart Health Program.[5,9] In this paper, the question of whether residents of the comparison community have become more health conscious—especially with respect to CVD—is the focus.

Methods

The Pawtucket Health Heart Program conducts a series of biennial surveys to assess relevant behaviors and cardiovascular risk factors in the study communities. Each of these surveys includes interviews and physiologic assessments of approximately 1,250 citizens between the ages of 18 and 65 in each of two New England cities, and spans the entire year in order to control for seasonal differences in physiologic risk factors. Households (defined as in the United States Census) are randomly sampled in each city using current listings known to be at least 95 percent complete. A single respondent from age-eligible members of the household is selected using tables adapted from Kish[10] and Deming.[11] A 15–20 minute interview includes questions about diet, exercise, smoking, CVD knowledge, availability of CVD-related programs, and sociodemographic characteristics. Measurements of height and weight, pulse, and blood pressure, and a 30 ml blood sample for later analysis of total cholesterol, triglycerides and HDL-cholesterol, are also obtained. The survey methods and their reliabilities are discussed in detail elsewhere.[12]

The data presented in this paper were collected in the four cross-sectional surveys conducted in the comparison city in 1981–82, 1983–84, 1985–86, and 1987–88. In addition, respondents to survey 1 were resurveyed after a lapse of five years: 61.3 percent completed the second examination. Each respondent was reexamined within one calendar month of the date of their first examination.

The percentage of participants answering favorably to questions were considered as dependent variables for surveys. Physiologic variables will not be analyzed until the final surveys are completed. Potential covariates employed in the analyses were: age, gender, education, language spoken at home, ethnicity, marital status, employment status, and household income level.

The objectives of this report are to document awareness, knowledge and behavior changes over time and determine trends. To measure the linear trend, the slope was calculated by weighted linear regression for each dependent variable, and tested with the Chi-square statistic.[13,14]

To adjust for potential covariate effects, eight groups were constructed. The cutpoints were investigated carefully so that: (a) each group had enough observations, and (b) the differences between distribution of surveys were preserved. The linear trend was calculated for each group and then an adjusted overall measure of linear trend across all groups was taken as the weighted average of the eight trends.[15]

[a] Due to budgetary constraints, S4 was extended to two years. Only data from the first half of the survey (1987–88) are reported.
*p ≤ .05
**p ≤ .01
Results expressed as percentages unless otherwise noted.

Results

A total of 5,070 persons participated in one of the cross-sectional surveys in the comparison city. Preliminary analyses were performed for each covariate. Gender distribution and marital status were similar across the four surveys with females comprising 58 percent of the overall sample; approximately 60 percent of respondents were married.

Significant differences among the four surveys were noted for age group distribution, years of education and proportion of employed. Survey participants at the last survey tended to be younger, better educated and more often employed compared to the first one.

Persons of Portuguese descent comprised about 45 percent of the sample in each survey, and only 73 percent of the sampled population spoke English. There was no indication of significant changes in these variables across the surveys.

Using the weighted regression analyses to detect linear trends in CVD knowledge and behavior, a number of significant effects were found (see Table 1). When each of these linear relationships was adjusted for the covariates (i.e. age, education level and employment status), similar trends were found for each variable.*

The expected changes in the population from regression analysis of changes in the cross-sectional surveys were compared with the actual changes found among cohort survey respondents.* The data indicate that, in most cases, the observed change in the cohort exceeded the expected value derived from the cross-sectional surveys.

Discussion

These results support the conclusion that important secular changes are occurring in cardiovascular health awareness, knowledge and behavior. It appears that such effects are not due to the increased presence of prevention programs either at participants' worksites or religious and social organizations and are likely attributable to programs mediated through electronic and print mass media.

---

*Data available on request to authors.

Respondents in the cohort survey demonstrated greater changes in health promotion knowledge and behavior than expected from cross-sectional survey data. This may reflect a self-selection bias among those persons who were reexamined, although the first examination may also have induced more health consciousness among this group.

The large proportion of persons of Portuguese heritage is a factor that limits generalizing these data to other sections of the region or country. The high proportion of respondents who spoke a foreign language at home raises the possibility that our estimates of the "secular trend" for CVD prevention-related awareness, knowledge and behavior are conservative. In more homogeneous, affluent, and educated communities, even greater effects may have occurred in the six-year period studied here.[16]

These observations support other studies of changes in awareness, knowledge and behavior among the general public.[8] That these changes are occurring in a city that serves as a comparison area for a population-based CVD research and demonstration project may reduce the power to detect the effects of intervention in the intervention community.[17-21] □

Sexual Risk Behaviors, AIDS Knowledge, and Beliefs about AIDS among Runaways

Mary Jane Rotheram-Borus, PhD, and Cheryl Koopman, PhD

ABSTRACT

Sexual risk behaviors, knowledge of acquired immunodeficiency syndrome (AIDS), and beliefs about AIDS prevention were examined among 126 runaways. In the previous 3 months, 65 percent of youths had been sexually active. Among the sexually active runaways, males reported a median of 2.7 partners and females reported 1.3 partners, and only 18 percent reported consistent condom use. Runaways demonstrated moderately high AIDS knowledge and beliefs endorsing AIDS prevention. Condom use and abstinence were directly related to beliefs about preventing AIDS. (*Am J Public Health* 1991;81:206–208)

Introduction

In 1988, runaways in New York City (NYC) were found to have human immunodeficiency virus type 1 (HIV-1) seropositivity rate of 6.7 percent.[1] This finding identified runaway youths as a high-risk group for HIV-1 infection. To design effective prevention programs, more information is needed on the sexual risk behaviors of these youths. However, empirical data documenting their risk behaviors are limited to a few items in epidemiological studies of runaways.[2–4]

Knowledge of AIDS and beliefs about AIDS prevention are relevant to reducing HIV-1 infection.[5,6] Therefore, the goals of this paper were to document runaways' current sexual risk behaviors, knowledge, and beliefs about preventing AIDS, and to examine the relationships among these findings.

Methods

Sample

The sample includes consecutive admissions to two of three residential shelters for runaway youths in Manhattan and Brooklyn over an 8-month period in 1988–89, for a total of 64 males and 66 females. They were recruited by two young adult Black interviewers, one male and one female, of whom both had intensive training in psychosexual assessment.[7] Two runaway males refused to participate in the study. Each sample contained primarily Black (65 percent) and Hispanic youths (28 percent). They ranged in age from 11 to 17, and 70 percent were born in NYC. The average age was 15.7 (SD = 1.5), and the median education completed was sophomore year of high school. Only 22 percent of runaways had ever lived "on the street"; however, 75 percent had not lived with a parent or guardian for at least 2 weeks.

Sexual Risk Behavior Assessment

A semistructured interview guide, *the Sexual Risk Behavior Assessment Schedule–Youth* (SERBAS),[8] was used to elicit information about sexual behavior. In this study, assessments of current sexual activity were limited to acts in which the exchange of semen or vaginal fluid was possible (i.e., oral, anal, and penile-vaginal intercourse), although these acts may not be of equal risk. Sexual behaviors assessed over the previous 3 months included abstinence, number of sexual partners, number of sexual encounters, and frequency of condom use (assessed on a 4-point scale based on number of sexual encounters divided by instances of condom use). Test-retest reliability conducted on items readministered to 22 runaways after 1 week was high (r ranged from 0.71 to 1.00).

General Knowledge about AIDS

A true-false instrument containing 62 items was used to assess general AIDS knowledge. The process of developing the instrument helped to address its validity, resulting in high internal consistency and test-retest reliability, as described elsewhere.[9] This instrument covers six domains: definitions, outcomes, risk behavior, transmission, prevention, and HIV-1 testing.

Beliefs about Preventing AIDS

Beliefs about AIDS and safer sex practices were assessed with 39 Likert-type items. This measure was developed in parallel procedures with the AIDS knowledge instrument. Previous research[9] using this instrument with runaway adolescents showed that it has high internal consistency. It covers five domains: peer support for safe acts, self-efficacy, self-control, perceived threat, and expectation of acting to prevent pregnancy, which is included because some of

TABLE 1—Frequencies of High-Risk Sexual Behavior during the Past 3 Months among Sexually Active Runaways[a]

Behavior	Males (N = 44)	Females (N = 37)
Sexually active	70%	59%
Number of partners		
Median	2.7	1.3
Mean ± SD	4.7 ± 6.0	2.0 ± 3.1
Number of sexual occasions		
Median	9.0	5.3
Mean ± SD	14.9 ± 20.6	9.9 ± 12.8
Condom use, percent		
Never	27.0	47.2
Sometimes	35.1	13.9
Most of the time	21.6	19.4
Always	16.2	19.4

[a] Sexual activity includes oral, anal, and vaginal intercourse. Data apply only to sexually active runaways. Thirty percent of the 63 male runaways and 41 percent of the female runaways in the total sample reported no sexual activity.

TABLE 2—Means and Standard Deviations of General Knowledge of AIDS and Positive Beliefs about Preventing AIDS among Male and Female Runaways

Variable	Males (N = 61)	Females (N = 64)
General knowledge	73% ± 12.9%	74% ± 11.6%
Belief domains		
Total positive beliefs	120.2 ± 13.6	122.3 ± 14.5
Peer support	16.1 ± 3.2	16.0 ± 3.8
Self-efficacy	63.4 ± 8.4	63.3 ± 7.7
Perceived threat	10.4 ± 2.0	10.4 ± 1.8
Self-control	16.2 ± 2.8	17.0 ± 1.8
Prevent pregnancy	14.7 ± 3.0	15.6 ± 3.8

the major strategies for preventing pregnancy (abstinence, avoiding sexual intercourse, and condom use) also reduce risk for HIV-1 infection.

Data Analysis

The frequencies of high-risk sexual behaviors were calculated for male and female runaways. One male and three females who reported exclusively homosexual activity were removed from analyses of sexual risk behaviors because their sexual behavior was not comparable to that of the heterosexual runaways. Chi square tests were computed on sexual risk behaviors, splitting the data on the number of sexual partners and number of sexual encounters at the joint median. T-tests examined gender differences on AIDS knowledge and on overall and domain scores for beliefs about AIDS prevention. Regressions were computed between overall knowledge and belief domain scores with sexual risk behaviors.

Results

The majority of these high-risk youths had been sexually active in the previous 3 months (see Table 1). Sexually active males reported a median of 2.7 sexual partners and 9.0 sexual encounters, and sexually active females reported a median of 1.3 sexual partners and 5.3 sexual encounters; 65 percent of the females and 32 percent of the males had only one partner. Among the sexually active youths, consistent condom use was low, although 47 percent of males and 44 percent of females reported using a condom the last time they had sexual intercourse. No runaways reported bisexual activity in the previous 3 months.

Table 2 shows the overall AIDS knowledge scores and overall and domain-specific beliefs of male runaways and female runaways. Youths showed moderately high general knowledge ($\bar{X}$ = 45.4, SD = 7.6, [a score that reflected 73 percent accurate knowledge]). Positive beliefs about preventing AIDS were also high ($\bar{X}$ = 121.4, SD = 14.1, [reflecting a 70 percent positive endorsement of safe acts]). There were no significant differences between the male and the female runaways on these measures.

Although the sexual risk behaviors were not significantly related to overall AIDS knowledge, condom use showed a weak inverse relation to perceived threat (B = −.17, 95 percent CI = −.33, −.01), and expecting to act to prevent pregnancy was positively associated with condom use (B = .14, 95 percent CI = .07, .22) and with abstinence (B = .05, 95 percent CI = .02, .07).

Discussion

Because previous research[3] has shown that intravenous (IV) drug use is not high among runaways in NYC, sexual activity is likely to be their primary risk behavior for HIV-1 transmission. The runaways' sexual risk behaviors, AIDS knowledge, and beliefs about AIDS do not provide a sufficient explanation for the high seroprevalence rate reported in 1988 (6.7 percent). Even though the runaways evaluated in this study were drawn from a residential shelter other than the one where the 6.7 percent seroprevalence rate was found, there is no reason to believe that the youths in our sample differ from those in the prevalence study. They were similar in age, ethnicity, and socioeconomic status, and many had been seen at the shelter where the seroprevalence study was conducted.

While most (65 percent) had been sexually active during the previous 3 months, the rate was not dramatically different from the percentage of a comparable sample of high school students who had been sexually active in the previous 6 months (58 percent).[10] Although condom use was relatively inconsistent, again, it was not different from condom use among adolescents in general.[11] Sexually active runaway girls typically have reported only one partner in the past 3 months. Furthermore, runaways' moderately high knowledge and positive beliefs about AIDS prevention were similar to those of high school samples.[10,12] This pattern of results suggests the need for more detailed studies examining the social networks from which these youths draw their sexual partners. Future research must also examine this population's drug use, including IV drug use, needle sharing, and crack use, as well as their exchange of sex for drugs or money.

These data do point to the importance of developing specialized programs for male runaways. Males have significantly more sexual partners compared with runaway females, consistent with findings on the number of lifetime sexual partners in a national sample of male adolescents.[13] However, the percentage of males in the study who used a condom the last time they had sexual intercourse (47 percent), was less than reported by adolescent males in a national survey (58 percent).[14]

Consistent with previous research,[15] we found moderate relationships between beliefs about preventing AIDS and sexual risk behaviors. Although as a group, the runaways had a fairly high knowledge of AIDS and had positive beliefs about AIDS, some youths were relatively uninformed. Interventions with these youths may impact behavior. ☐

Security Measures for AIDS and HIV

Carl G. Torres, PhD, Mark E. Turner, MPH, John R. Harkess, MD, and Gregory R. Istre, MD

ABSTRACT

This study describes the measures being taken by AIDS surveillance offices across the country to ensure the security of information regarding patients with AIDS and HIV infection. Security measures were evaluated according to the cumulative number of AIDS cases reported, whether partner notification services were provided, and whether HIV seropositive reporting by name was also required. This study showed that public health departments have taken extra steps to ensure the security of AIDS and HIV data. (*Am J Public Health* 1991; 81:208–209)

Introduction

Public health surveillance for acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection has accentuated the need for confidentiality and security of health records. This study describes the measures being taken across the country to ensure the security of information regarding patients with AIDS and HIV infection reported to public health departments. Security measures were evaluated according to the cumulative number of AIDS cases reported, whether partner notification services were provided, and whether HIV seropositive reporting by name was also required.

Methods

The study population comprised all 66 AIDS surveillance offices responsible for reporting to the Centers for Disease Control as of July 1, 1989. These offices were located in 13 city/county health departments, all 50 state health departments, the District of Columbia, Puerto Rico, and Guam. Confidential questionnaires solic-

iting information regarding security measures used to protect AIDS and HIV data were sent in mid-July 1989. A reminder letter was sent in mid-August 1989 and reminder telephone calls were placed during the last week of August 1989. Security measures were examined by the number of cumulative AIDS cases reported to the specific office as of June 30, 1989 (less than 500, between 500 and 1,500, and greater than 1,500), whether provider referral partner notification (PRPN) was offered, and whether HIV seropositive reporting by name was required.

Results

Questionnaires were returned by 63 (95 percent) of 66 AIDS surveillance offices. All offices maintained their records in locked cabinets. In addition, an array of other measures were employed to protect written and computer records (Table 1). Where all HIV infections were reportable, 95 percent of the offices handled HIV reports in the same way as their AIDS case data. There were 26 offices with fewer than 500 AIDS cases reported, 20 offices with 500 to 1,500 cases, and 17 offices with over 1,500 cases. Forty-six offices (73 percent) provided PRPN. The median number of AIDS cases reported in offices with PRPN was 499, while the number for offices without this service was 1,400. Reporting of all HIV infections was required by 21 offices. The median number of AIDS cases in the 21 offices was 550, while in the offices without HIV reporting the median number was 1,273. The proportion of security measures utilized did not differ significantly with respect to the cumulative number of AIDS cases reported, whether PRPN was offered, or whether all HIV infections were reportable.

Discussion

This study showed that public health departments have taken steps to ensure the physical security of records regarding patients with AIDS and HIV infection. As a minimum, records were maintained in locked cabinets, however, most offices had instituted additional safeguards, such as restricting access to areas where AIDS records are stored, bar locks, alarms, and computer security systems.

No statistically significant differences were found in the proportion of security measures with respect to the cumulative number of AIDS cases reported, whether PRPN was offered or whether reporting of HIV infection was required. This indicates that the implementation of PRPN and HIV reporting is being done without compromising the physical security of records. The results of this study provide a tool with which public health departments and others holding highly sensitive personal health data can appraise the measures taken to ensure the security of their records. Although this study does not address procedures being taken to ensure security of data among field staff or in settings outside public health departments, it does indicate that public health officials are taking extra measures to ensure the physical security of data regarding patients with AIDS and HIV infection. ☐

Acknowledgments

This research was supported by Grant U621CCU602027-05 from the Centers for Disease Control. The authors wish to thank the personnel from each of the surveillance offices that participated for their cooperation. The preliminary findings of the pilot survey for this study were presented at the annual meeting of the Conference of State and Territorial Epidemiologists held in Oklahoma City, May 1989.

Discharges against Medical Advice at Regional Acute Care Hospitals

David Barton Smith, PhD, and Joel Leon Telles, PhD

ABSTRACT

Data from 67 acute care hospitals in the Philadelphia metropolitan area indicate that there were 7,613 discharges against medical advice (AMA) in fiscal year 1987, or 1.20 percent of all discharges that year. Diagnosis-related group (DRG), type of insurance, and sex had independent effects on the rate of AMA discharges. Urban community hospitals had the highest percent of AMA discharges. Previous studies, done in teaching facilities, may have underestimated the rate of AMA discharges. (*Am J Public Health* 1991; 81:210–213)

Introduction

Discharges against medical advice (AMA) represent a frustrating problem for the individual physician and hospital, and an overlooked indicator of potential problems facing the organization of public health services in a region. Little systematic analysis of the subject has been published. Most reports have been anecdotal or limited to specific diagnostic groups within a few selected institutions.[1-3] The only published general estimate, based on a 2-year review of records in a major teaching institution, reported that patients who were discharged AMA accounted for about 0.8 percent of discharges.[4] We analyzed regional data to describe regional patterns and, because larger numbers were involved, to help clarify the relative influence of factors associated with variation in AMA rates.

Methods

A systematic description of patients discharged against medical advice from acute care hospitals was generated from the comprehensive regional inpatient data base constructed directly from hospital abstract tapes supplied to the Delaware Valley Hospital Council. We analyzed the data on the 635,897 patients discharged from all 67 acute care hospitals in the Greater Philadelphia area between July 1, 1986, and June 30, 1987. We used a linear modeling approach, applying the categorical modeling procedure in the SAS statistical package, to estimate the independent effects of diagnosis-related group (DRG), payment method, and sex on the percent of AMA discharges.[5,6]

Results

A total of 7,613 cases, or 1.20 percent of inpatient discharges, were listed as discharged AMA. Males were more than twice as likely as females to be discharged AMA (Table 1). Patients who were covered by the Medicaid program or who had no insurance were three times as likely to be discharged in this manner.

AMA discharges were concentrated in a few diagnostic categories. Table 2 lists the 20 DRGs with the highest frequency of AMA discharges according to the Medicare prospective-payment grouper procedure in effect October 1, 1987, to September 30, 1988.[7] These 20 DRGs accounted for 60.7 percent of AMA discharges. Major diagnostic category (MDC) 20 (DRG 433-437), alcohol and drug use and alcohol- and drug-induced organic mental disorders accounted for 26.6 percent of AMA discharges and was the MDC with highest percentage of patients with such discharges (14.6 percent).

The average length of stay for AMA discharges was about half the average length of stay for all discharges in most of the 20 DRGs. The DRG case weight for all AMA discharges was 0.77, compared with 0.99 for all discharges in the region, suggesting that they were somewhat less severe.[8] However, it is also possible that many such discharges led to later readmissions, as noted in studies of psychiatric facilities.[9]

Among the 20 most frequent AMA discharge diagnoses, diagnosis, insurance status, and sex of the patient had statistically significant ($p < .001$) independent main effects. The Medicaid and self-pay discharges represented underinsured groups in the Philadelphia area with similar patterns of use, and they have been combined in this analysis. The estimate of the percent of AMA discharges for any combination of these three variables can be calculated by adding the individual effects.

Thus, in Table 3, the estimate for the percent of AMA discharges for male Medicaid cases with DRG 430 (psychoses) is 8.00 percent (INTERCEPT [4.12 percent] + DRG [2.19 percent] + MEDICAID/SELF-PAY [1.35 percent] + MALE [.35 percent]. The actual percent of AMA discharges for this group of cases was 7.89 percent, and the standard error for the es-

timate was 0.24 percent. For all 20 of these discharge diagnoses, estimates of the effect of the DRG category on the percent of AMA discharges ranged from 9.56 percent for substance abuse admissions falling into MDC 20 to −2.29 percent for DRG 243 (medical back problems). The effect of Medicaid or self-pay status (1.34 percent) was almost four times greater than the effect of being male (.35 percent).

AMA discharge rates also varied significantly by the geographic location and the type of facility. Suburban and teaching hospitals had the lowest rates of AMA discharges. Urban community hospitals had the highest rates. Table 4 presents the percent of AMA discharges by type of hospital for the 24 MDCs. Except for the group of specialty facilities (800 beds out of a regional total of 17,555 beds, the majority belonging to two children's hospitals), suburban facilities had the lowest AMA rates. In contrast, the urban community hospitals had the highest percent of AMA discharges (3.49 percent compared with 1.20 percent for the region as a whole). Teaching facilities tended to have lower rates of AMA discharges than community hospitals. The differences in rates of AMA discharges between urban and suburban hospitals and between community and teaching hospitals persist in almost all MDCs.

Discussion

While the analysis confirms the patterns found in the previous case studies of self-selected institutions, it places the findings into a broader perspective.[1-4] Because previous inquiries studied major teaching institutions, they may have underestimated the magnitude of the problem. The 1.2 percent of Philadelphia-area discharges that were AMA is substantially higher than the 0.8 percent found in the previously cited Peter Bent Brigham Hospital study. Urban community hospitals located in areas with the most serious problems of social disorganization (e.g., crime, drug addiction, unemployment) had the highest rates.

AMA rates do not appear to be simply a function of the disease and the nature of its treatment. Males, Medicaid patients, and patients identified as self-paying were more likely to be discharged AMA, independent of diagnosis. They represent a crude measure of therapeutic failure or, at least, failure in the provider-patient relationship. Efforts to reduce these discharges must be balanced against the individual rights of patients to refuse treatment, the legitimacy of some of the personal reasons that motivate them to leave, and the potential harm to the patient of premature discharge.

It is useful to view AMA discharges in the context of overall patterns of use and access to health care. Indeed, there is a striking symmetry between the factors

affecting "entrance" to health services (i.e., barriers and delays in seeking care and overall patterns of underutilization) and of the factors affecting AMA discharge rates, which may be viewed as inappropriate "exit" from such services.[10-14]

Since regional data systems are now widely available, it is possible to monitor these processes more systematically. These rates can be linked more directly to the relationships between medical and social problems in regional populations and to the pressures imposed on medical management by different forms of reimbursement as they change the character of inpatient care. AMA discharges represent many of the problems (e.g., those related to drugs, alcohol, psychiatric conditions, and indigent care) that public health agencies address. The percent of AMA discharges may in time take its place among other indicators of incidence rates and use of health services in a population and help document progress (or the lack of it) in solving larger social problems. ☐

An Evaluation of the Use of the Statewide Planning and Research Cooperative System of New York State as a Resource Planning Tool for HIV Infection

Gerald I. Kaufman, PhD, MCS, George T. DiFerdinando, Jr, MD, MPH, and Sarah E. Gottesman, MS

ABSTRACT

Hospital discharge records of patients with *Pneumocystis carinii* pneumonia (PCP) in New York State were studied to determine whether cases of human immunodeficiency virus (HIV) infection were identified. We estimate that as many as 13 percent of hospitalizations of patients with PCP in 1987 and 10 percent of those in 1988 were not appropriately identified as HIV related. Identification of PCP as HIV related was a function of a hospital's volume of PCP admissions. (*Am J Public Health* 1991;81:213–215)

Introduction

One means of estimating acute care hospital use in New York State by patients infected with human immunodeficiency virus (HIV) has been based on the Statewide Planning and Research Cooperative System (SPARCS).[1] SPARCS, a mainframe data base that has been in existence since 1980, contains a discharge abstract for more than 95 percent of the acute care hospital stays in the state, exclusive of those occurring in federal and psychiatric acute care facilities. The discharge abstracts describe the hospital patient's medical condition in five diagnostic fields, including a principal diagnosis and four secondary diagnoses, using ICD-9-CM diagnostic codes.

In October 1986, new HIV-specific ICD-9-CM codes[2] became effective.[3] The new codes, 042-044, indicate the presence of certain illnesses and/or conditions occurring simultaneously with HIV infection,

[b] HIV-estimated PCP divided by PCP discharges multiplied by 100.

[c] Background considered 82.5 percent reported (78 PCP discharges).

and another, 795.8, indicates an HIV-seropositive test result. The purpose of this study was to estimate the completeness with which admissions of HIV-infected patients were identified in the SPARCS.

Methods

We studied the completeness of HIV identification in admissions for *Pneumocystis carinii* pneumonia (PCP) in SPARCS during 1987 and 1988. PCP was extremely rare prior to the HIV epidemic[4–6]; it is now the most frequently found illness in persons with acquired immunodeficiency syndrome (AIDS).[7] Each SPARCS discharge record with a diagnosis of PCP infection (ICD-9-CM code 136.3 in the principal or secondary diagnosis fields) was considered to represent a PCP admission. Each PCP discharge with an ICD-9-CM code of 042-044 or 795.8 in the principal or secondary diagnosis fields was considered to be a PCP admission identified with HIV infection.

To establish the expected number of HIV-related PCP discharges in the given year, we subtracted the estimated number of non-HIV not-related PCP discharges from the reported number. We estimated this "background" frequency of non-HIV-related PCP discharges by counting the number of PCP discharges in 1980; we assumed such discharges to be non-HIV related. We assumed the number non-HIV-related PCP discharges had not substantially changed since 1980.

We studied the validity of the assumption that the annual number of non-HIV-related PCP discharges remained essentially unchanged in two ways. First, we compared the 1987 and 1980 PCP admissions from New York State counties that reported fewer than two AIDS cases through 1987 to the New York State AIDS Registry. If our assumption was correct, there should have been little or no difference in the number of PCP discharges by these counties in the 2 years.

Second, we reviewed the extent of HIV identification in PCP discharges in the "most sensitive" hospitals, those with the most experience with PCP in 1988. If our assumption was correct, the number of non-HIV-identified PCP discharges in such hospitals should be consistent with our 1980 background estimate.

We also investigated whether the percentage of PCP discharge abstracts with an ICD-9-CM code indicating HIV infection was associated with a hospital's experience with PCP. Hospitals were grouped into 11 different experience levels for each year studied. Linear regression using SAS[8] was performed to determine if a relation existed between PCP experience, year, and HIV coding.

Results

Completeness of HIV-Infection Identification

Non-HIV-related PCP Rates—In 1980, 94 discharges with a PCP diagnosis were reported to SPARCS. At that rate, one would expect non-HIV PCP background level of 1.6 percent in 1987 and 1988.

Eight of the 62 counties in New York State reported fewer than two AIDS cases to the New York State Registry through 1987. In 1980 each of these eight counties reported no PCP discharges. In 1987, four of the[se] eight counties reported no PCP discharges, three reported one PCP discharge, and one reported two PCP discharges.

Our review of the two hospitals with the largest number of PCP discharges (277 and 241) in 1988 revealed that HIV was associated with 97.4 percent and 99.6 percent of the PCP discharges.

PCP Discharges and HIV Codes—The results are shown in Table 1. After correction is made using the non-HIV PCP background, 98 percent of PCP discharge records in 1987 and 1988 should have been identified with an HIV diagnosis. Only 87 percent of the 1987 PCP discharge records and 90 percent of the 1988 records included an HIV diagnosis. Thus, up to 13 percent more of the 1987 and 10 percent more of the 1988 PCP discharge records should have contained an HIV-infection code.

Hospital Experience

Two linear regression models were considered. The first included year and hospital PCP volume as independent variables and percentage HIV identified as the dependent variable. A borderline significant effect was noted for year (β = 5.00, SE = 2.63, p = .07). Utilizing the

Note: Data obtained from the New York State Statewide Planning and Research Cooperative System (SPARCS). Data for 1988 are 80–85 percent complete.

data available from both years, a reduced model was then considered that contained only hospital PCP volume as the independent variable (Table 2). Results from that model indicated a positive association between hospital PCP volume and percentage HIV identified ($\beta = 0.93$, SE = 0.45, p = .049).

Discussion

After correcting for the non-HIV-related PCP discharges, we have found undercoding of HIV infection in discharge abstracts of PCP-identified patients in New York State's acute care facilities. The amount of undercoding was a function of the facility's volume of PCP patients.

Our estimate of HIV-related PCP discharges depended on our assumption that the number of non-HIV-related PCP discharges was essentially constant statewide between 1980 and 1988. The results from our review of PCP occurrence in counties with a low incidence of AIDS and in hospitals with a high occurrence of PCP are consistent with such an assumption. However, there may be secular trends in non-HIV-related causes of PCP that affect the background level. Review of diagnoses in the SPARCS records of non-HIV-identified PCP patients is not sufficient to determine the presence or absence of HIV infection.

The reasons for the hospital variations in reporting PCP patients as HIV infected are unknown. In the interest of confidentiality, a hospital may choose to report that a patient was not HIV-positive even though the condition was diagnosed or suspected. A lack of sufficient number of diagnostic fields in SPARCS may also be a factor, since many PCP patients are sufficiently ill with other conditions that could fill the principal and four secondary diagnosis fields of the SPARCS record. However, since the inclusion of an HIV diagnostic code would increase reimbursement substantially, HIV coding should take precedence by hospitals when its presence is known.

Another explanation is that even at this late date in the HIV epidemic, providers in New York State do not recognize that PCP patients demonstrate the most publicized HIV-related opportunistic infection. If so, other, more subtle sequelae of HIV infection may be being identified at an even lower rate, and treatment of HIV-infected patients may be delayed. Further study of the non-HIV-infected PCP patients would clearly be fruitful. In the absence of such a study, it is prudent to recognize that statewide HIV hospitalization utilization may be underestimated when SPARCS or a comparable system is used as the source. ☐

Survival Trends of People with AIDS in Washington State

William E. Lafferty, MD, David Glidden, BA, and Sharon G. Hopkins, DVM, MPH

ABSTRACT

Survival rates of 609 cases of acquired immunodeficiency syndrome (AIDS) in Washington State diagnosed between 1982 and 1987 according to pre-1987 AIDS surveillance definition were analyzed. People with a primary diagnosis of Kaposi's sarcoma survived longer than those with *Pneumocystis carinii* pneumonia. Both groups survived longer than those with other diagnoses. Median survival increased from 11.3, to 12.5, to 20.8 months for cases diagnosed in or before 1985, during 1986, and during 1987, respectively. (*Am J Public Health* 1991; 81:215–218)

Introduction

In Seattle-King County, the major metropolitan area in Washington State, acquired immunodeficiency syndrome (AIDS) was the third leading cause of death in males aged 25–44 years in 1986. In 1987, it was second, according to the King County Department of Vital Statistics. While AIDS continues to increase in importance as a cause of mortality,[1] therapeutic advances should eventually be reflected in decreased mortality and longer survival times. Such trends have been reported from major epicenters of the epidemic, such as San Francisco,[2] and may be occurring nationwide.[3] Our study confirms that survival times of persons living

with AIDS have increased in Washington State independent of changes in the AIDS case definition.

Methods

The Washington State and Seattle-King County human immunodeficiency virus (HIV)-AIDS epidemiology units maintain [a] registry of case reports that meet the Centers for Disease Control (CDC) surveillance definition of AIDS. All resident cases were investigated. Survival analysis was performed only for patients 13 years of age or older that met the pre-1987 case definition.[4] Cases with more than one primary diagnosis were classified by hierarchy into one of three categories: *Pneumocystis carinii* pneumonia (PCP), other diagnosis without PCP, or Kaposi's sarcoma (KS) alone. Passive AIDS case reporting was estimated to be 96 percent and 88 percent complete in 1986 and 1988, respectively, according to methods previously described.[5]

In December 1988 all presumed surviving cases diagnosed on or before December 1987 were investigated. Provider contact and telephone surveillance are routine and update mortality status yearly. County vital records were reviewed for recent deaths that were either unknown to providers or may not have reached the state's vital records office. County vital records yielded 10 unreported deaths among 286 persons with AIDS who were presumed living after provider contact. Three cases lost to follow-up were censored at the last date known to be alive.

Cohorts were formed of individuals diagnosed in 1985 or before, individuals diagnosed in 1986, and individuals diagnosed in 1987. The groups were compared by means of nonparametric rank tests for censored data[6] after adjusting for primary diagnosis but not for any other prognostic variables. The effect of year and diagnosis was also estimated by fitting the Cox proportional hazards model. Hazard comparisons are relative to cases diagnosed before 1986 with KS and were made using BMDP2L.[7] Because of the limited amount of data available on any given subject, our ability to investigate and adjust for prognostic variables was limited.

The CDC case report forms record the month and year in which an individual is diagnosed and the day, month, and year of death. Approximate survival times were constructed by assuming that all individuals were diagnosed on the 15th of the month. For the generalized Wilcoxin test this is equivalent to breaking tied death times (tied if counted in months) in favor of individuals who died later in the month. These approximate death times were also used to produce Kaplan-Meier survival curves using PROC Lifetest[8] and to produce the relative hazard estimates.

Results

Through the end of 1987, 777 adult AIDS cases had been reported; 680 met the pre-1987 AIDS case definition. Seventy-one of these cases died within 1 month of diagnosis. Mean age at the time of diagnosis, racial composition, sex, and transmission category of the three temporal cohorts did not change significantly between the intervals (Table 1). Although the proportion of intravenous drug users (IVDUs) increased from 1 percent to 3

TABLE 3—Relative Hazard Table of Cohort Survival

Data	Relative Hazard	95% CI
Primary diagnosis		
KS	1.00	—
PCP	1.46	1.22, 1.91
Other diagnosis	2.20	1.63, 2.96
Year of diagnosis		
≤1985	1.00	—
1986	0.68	.545, .852
1987	0.39	.304, .497

percent from 1985 to 1987, only 12 IVDUs were included in the study. Overall, the proportion of cases diagnosed as outpatients increased from 11 percent to 20 percent between 1985 and 1987. Of definitively diagnosed cases of KS, 19 percent, 26 percent, and 68 percent were diagnosed as outpatients before 1986, in 1986, and in 1987, respectively (data not shown).

Overall, cases survived a median of 14.4 months (Tables 2 and 3). People with KS survived longer than people with PCP. Both groups survived longer than those with other diagnoses. Survival increased in cases diagnosed in more recent years. Cases of PCP and other diagnoses that were diagnosed during 1989 had longer survival times than those diagnosed in 1986 ($p < .001$, for each comparison). Most people with KS diagnosed in 1987 were still living. Median survival for inpatient cases with primary diagnoses of PCP increased from 12.4, to 15.8, to 20.8 months for the three time intervals, respectively ($p < .0001$).

Discussion

We believe our ascertainment of deaths was fairly complete. Although recent out-of-state deaths could have been missed by these methods, the impact of these cases would be 5 percent or less. In addition, since completion of this study, cases have been matched to the National Death Index. Only two deaths were detected that were not included in this analysis.

Our data confirm that trends seen in major epicenters of the AIDS epidemic are occurring elsewhere in the United States. Increases in survival for people with primary diagnoses of PCP could be related to PCP prophylaxis and zidovudine therapy. Local zidovudine studies treated approximately 52 residents who had PCP diagnosed in 1986. The lack of increase in the median survival of people with other diagnoses from 1985 to 1986 may reflect their ineligibility for zidovudine studies.

Although studies in San Francisco have shown a decrease in median survival for people with KS through 1985 and slight increases during 1986 and 1987,[2] our KS cohort diagnosed in 1986 survived longer than those diagnosed during or before 1985. The increase in outpatient diagnoses of KS from 1985 to 1987, from 19 percent to 68 percent, suggests this practice may in part be responsible for our local data. The general availability of zidovudine in March 1987 may be responsible in part for the sharp increases in survival seen in 1987. Exclusion of outpatient diagnoses for people with PCP did not reduce median survival; therefore, earlier diagnosis is an unlikely reason for prolonged survival in this cohort.

The impact of prolonged survival of people living with AIDS on the health care system needs evaluation. Although CDC case projections for 1990 and beyond have been reduced in cumulative numbers by 16 percent through 1993,[9] increased survival may neutralize the effect of fewer new cases on the health care system. Recent federal registration (H.R. 2310) expanding insurance continuation from 18 to 29 months may make health care more accessible to a larger number of people living with AIDS who survive longer than 18 months. However as the use of zidovudine and other antiviral drugs prolongs survival, health care programs need to provide long-term access to people who are otherwise uninsurable. ☐

New from NCHS

Long-term Care for the Functionally Dependent Elderly

Introduction

Greater attention has focused recently on financing of long-term care, due both to the growing burden to society and individuals and to the increasing size of the elderly population at risk of needing long-term care. As a result, insurance companies underwriting private long-term care insurance policies, legislators, and other policy makers need estimates of the population most at risk of needing long-term care. A recent report from the National Center for Health Statistics (NCHS) should help such policy makers plan for long-term care services.[1]

The report was based on combined data from the Supplement on Aging (SOA) to the 1984 National Health Interview Survey (NHIS) and the 1985 National Nursing Home Survey (NNHS). In brief, the NHIS is a continuing national survey of the health of people residing in households in the United States. The SOA was added in 1984 to obtain information about older persons that had not been available previously from a national survey. All persons age 65 years and over and half of those ages 55–64 in responding NHIS households were included in the SOA sample; 97 percent of those eligible participated in the SOA (16,148 people) of whom 92 percent responded for themselves. Descriptions of the NHIS and SOA have been published.[2,3]

Data on nursing home residents are from the 1985 NNHS, a national probability sample of nursing homes, their residents, discharges, and staff. Homes included in the NNHS were nursing and related care homes in the conterminous United States, without regard to the level of care, whether they participated in Medicare or Medicaid, or whether they were licensed. Board and care homes and residential care homes were excluded.

Nursing home resident estimates are based on the sample of 4,650 residents ages 65 years and over from the 1,079 nursing homes participating in the survey. Residents included in the sample were those on the nursing home's roster as of the night before survey. Data were collected by interviewing knowledgeable nursing home staff members, who referred to the residents' medical records when necessary. The response rate for the resident sample was 97 percent.[4]

The report profiles long-term care use by functionally dependent people age 65 years and over, where functionally dependent is defined as receiving human assistance with at least one activity of daily living (ADL) or instrumental activity of daily living (IADL). Persons who did not perform or were unable to perform the activity were also considered dependent. ADLs are the basic personal functions of bathing, dressing, eating, getting in or out of a bed or chair, mobility, using the toilet, and continence. IADLs are everyday activities that enable an individual to live independently in the community: preparing meals, shopping, managing money, using the telephone, doing light or heavy housework, and getting around outside the home.

Criteria used to define dependence in the ADLs and IADLs for noninstitutionalized people were largely based on those used in an earlier report on the physical functioning of the aged.[5]

Noninstitutionalized Elderly

Dependence in the ADLs for noninstitutionalized people was defined as: 1) having difficulty performing the activity because of a chronic condition and *receiving* help of another person in performing the activity; or 2) being unable to perform the activity without special equipment and not having that equipment. Dependence in the IADLs for this population was defined as having difficulty or inability to perform the activity without assistance because of a health problem.

Institutionalized Elderly

On the other hand, dependence in the ADLs for nursing home residents was defined as requiring (needing) assistance of another person or special equipment to perform the activity. Dependence in the IADLs for nursing home residents was defined as receiving personal help or supervision to perform the activity. For the purposes of this report, it was assumed that the effect of differences in question wording between the SOA and the NNHS ("receiving" versus "needing" help) was minimal because residents in an institutional environment are likely to receive assistance if they need it. It was also assumed that all nursing home residents were dependent in two IADL activities (preparing meals and doing heavy housework) routinely provided in nursing homes, even though not all residents were dependent in these activities.

Results

Based on combined estimates of the institutionalized and noninstitutionalized population of the United States, 29 percent of people age 65 years and over in

All functionally dependent elderly	8,051,100	29.0	100.0
Nursing home care	1,318,300	4.8	16.4
Formal home care[a]	1,662,500	6.0	20.6
Informal home care only	3,380,400	12.2	42.0
No long-term care	1,689,800	6.1	21.0

a) Includes persons receiving both formal and informal home care services.
ADL = activities of daily living
IADL = instrumental activities of daily living.

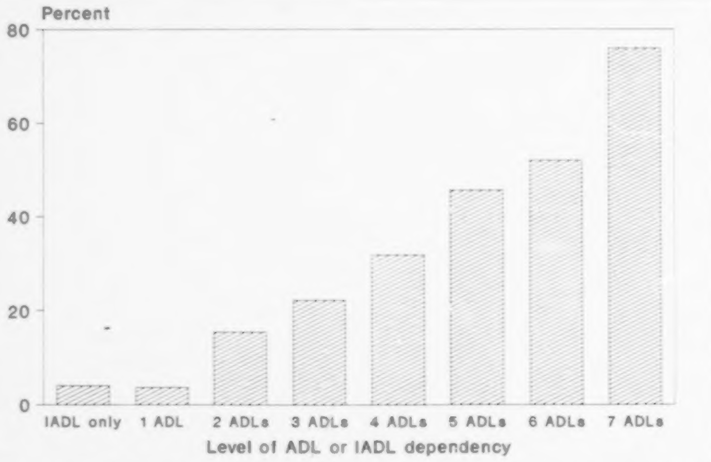

FIGURE 1—Percent of functionally dependent persons age 65 years and over residing in nursing homes by level of ADL or IADL dependency: United States, 1984–85

1984–85, or 8 million persons, were functionally dependent and at risk of needing long-term care services. About three-fourths of this population had only slight limitations in these functions; 49 percent were dependent in only one or two ADLs and 25 percent were dependent in only the IADLs. About 9 percent were moderately dependent, receiving assistance in three to four ADLs, while 17 percent were severely dependent, receiving assistance in nearly all ADLs and IADLs.

Although long-term care has traditionally meant nursing homes, it also includes the services of home health agencies, visiting nurses, adult day care centers and other community-based services, as well as care provided informally by family and friends. This report examined three types of long-term care: nursing home care, formal home care, and informal home care. Formal home care services were defined as receipt of paid-for personal assistance in performing at least one ADL or IADL, while help provided without compensation was considered informal home care. In 1984–85, 79 percent of the functionally dependent elderly population received long-term care services (Table 1). Informal home care by family and friends was the most commonly received type of long-term care (42 percent). About 21 percent received formal home care services, often in combination with informal home care. About 16 percent of the functionally dependent elderly resided in nursing homes. The percent of functionally dependent elderly persons receiving these three types of long-term care is much higher than that for the general elderly population. In 1984–85, the percent of elderly receiving informal home care was 12 percent, while 6 percent received at least some formal home care service. Only 5 percent of the elderly resided in nursing homes (Table 1).

The degree of dependency in the ADLs and IADLs was associated with the type of long-term care used by functionally dependent persons. Home care use was greater among those with only IADL limitations or four or fewer ADL limitations; nursing home use was greatest among those dependent in five to seven ADLs. There was a nearly linear relationship between the percent of functionally dependent elderly residing in nursing homes and the number of ADL dependencies. About 76 percent of the elderly dependent in all ADL functions were in nursing homes compared with 4 percent of the elderly dependent in only one ADL function (Figure 1). This finding, however, is affected by the fact that many nursing homes have policies that do not permit a resident to perform the ADLs or IADLs without assistance.

Because functional dependency in ADL and IADL activities is higher at older ages (from 20 percent among those ages 65–74 years to 66 percent among those ages 85 years and over), overall use of long-term care, and use of nursing homes in particular, was also higher at older ages. The percent of functionally dependent elderly using long-term care increased from 71 percent among those ages 65–74 years to 93 percent of those ages 85 years and over; nursing home use increased from 6 percent among those ages 65–74 years to 36 percent among those age 85 years and over. The average age of functionally dependent elderly in nursing homes was 83 years, while that of their counterparts using any formal or only informal home care services was 78 and 77 years, respectively. Besides age, other

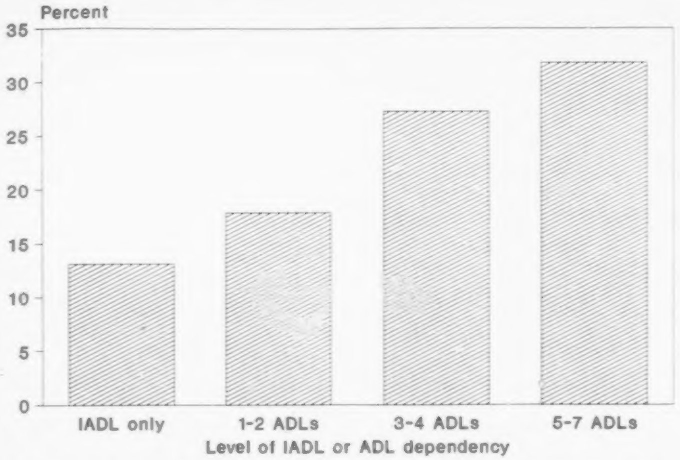

FIGURE 2—Percent of functionally dependent home care recipients receiving both formal and informal home care services: United States, 1984–85

factors found to be significantly associated with nursing home use were being female, White race, being unmarried, and having income below the poverty threshold.

Home care services (formal or informal) were used by a younger, less dependent population. Availability of an informal support network of family and friends appears to be associated with receipt of informal care; among the functionally dependent elderly, use of informal home care services was greater for males, for persons living with a spouse or others, and for married persons; use of any formal home care services was greater for females, for persons living alone, and for unmarried persons. The greater use of informal home care services by Black functionally dependent elderly coincides with their greater likelihood of living with spouse or others (potential caregivers). Functionally dependent elderly persons with income above the poverty threshold were more likely to use both formal and informal home care services.

Use of formal home care services, however, was also dependent on the level of ADL or IADL limitations. Formal home care services were used to augment informal care provided by family or friends more often among the severely dependent elderly than among those with few limitations. Thirty-two percent of home care recipients dependent in five to seven ADLs, and 27 percent of the elderly home care recipients dependent in three to four ADLs relied on both formal and informal caregivers, compared with 13 percent of home care recipients dependent in only the IADLs (Figure 2). Persons living alone were four to five times more likely to use only formal home care services than those living with spouse or others; persons living with spouse or others were more likely to receive only informal home care services.

Discussion

While this report presents a more complete picture of long-term care use by the functionally dependent elderly population than available by looking at only the nursing home or the community-dwelling population, the data have limitations in interpretation. First, there are reporting differences in the SOA and NNHS data; the surveys had different respondents (self-report versus nursing home staff), and the question wording was not always identical. Second, the two surveys were fielded in different years. This problem, however, should be negligible since the proportion of the noninstitutionalized population that was functionally dependent did not change between 1984 and 1986. Further research is possible by accessing public use data tapes for the 1984 SOA and the 1985 NNHS. The 1984 SOA can be obtained from the Division of Health Interview Statistics, National Center for Health Statistics in Hyattsville, Maryland. The 1985 NNHS can be obtained from the National Technical Information Service in Springfield, Virginia. Both data tapes are also available from the National Archive of Computerized Data on Aging (NACDA) from the Inter-university Consortium for Political and Social Research at the University of Michigan in Ann Arbor, Michigan. ☐

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription Price is $80/year US; $120/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Impact of the Minnesota Parental Notification Law on Abortion and Birth

James L. Rogers, PhD, Robert F. Boruch, PhD, George B. Stoms, BA, and Dorothy DeMoya, DNSc

ABSTRACT

Background. The impact of the Minnesota Parental Notification Law on abortion and birth was examined.

Methods. Using linear models, outcome parameters were compared before and after enactment of the law. Time by age group interactions also were examined.

Results. The pre-enactment to post-enactment change in the Minnesota abortion rate reflected a greater decline for minors (≤17 years old) than for 18–19 year-olds (who were not under the law). An increase in abortion rate occurred for women ages 20–44. The law appeared to have had no impact on birth rate in minors. Following the enactment of the law, the rate of early abortions (≤12 weeks) declined among minors more than the rate of late abortions (>12 weeks). This resulted in a pre-enactment to post-enactment increase in the ratio of late-to-early abortions among minors.

Conclusions. These data suggest that parental notification facilitated pregnancy avoidance in 15–17 year-old Minnesota women. Abortion rates declined unexpectedly while birth rates continued to decline in accordance with a long-term trend. (*Am J Public Health* 1991;81:294–298)

Introduction

Laws requiring parental consent or parental notification prior to legal induced abortion for minor women, collectively called parental involvement laws, exist or have been proposed in numerous states. As of July 1990, laws in the United States requiring parental consent were in effect in Alabama, Indiana, Louisiana, Massachusetts, Missouri, North Dakota, and Rhode Island. Laws requiring parental notice were in effect in Arkansas, Idaho, Utah, and West Virginia; and parental involvement statutes were under challenge in Arizona, California, Georgia, Illinois, Kentucky, Mississippi, Nevada, Pennsylvania, and Tennessee. National attention focused on these laws when statutes from Minnesota and Ohio were heard by the US Supreme Court during its October 1989 term resulting in a decision largely supporting these laws. The present paper concerns the Minnesota law, enacted in August 1981 and enjoined in March 1986. This law required a minor woman to notify both parents at least 48 hours prior to an abortion or else seek court approval.

Few empirical studies have evaluated the impact of parental involvement statutes on minor women. Cartoof and Klerman[1] determined that abortions to minors in Massachusetts declined dramatically (43 percent) following the enactment of a parental consent law. However, during this time an approximately equal number of women migrated to surrounding states to obtain abortions. Blum[2] found that under parental notification in Minnesota, communication with parents about a minor's planned abortion occurred more often than had been reported by Clary[3] in a Minneapolis/St. Paul study predating the law. But Blum found that patterns of communication differed little from those among teenagers simultaneously surveyed in the neighboring state of Wisconsin (without such a law).

Common negative claims about parental involvement laws are that they force minors to leave the state to obtain abortions (as in Massachusetts), and that they result in increased birth rates, late abortions and medical complications. These effects are presumably related to a minor's reluctance to discuss her pregnancy with parents.[4] Positive claims about these laws are that they promote responsibility (by encouraging teenagers to "think before they act"), foster parent-child communication, facilitate mature decision making, and may reveal medical history information that would otherwise remain unknown to the physician.[5,6]

Empirical evaluation of assertions like these will necessitate multiple studies under a variety of circumstances and localities. The Cartoof and Klerman study[1] was conducted in Massachusetts, located in close proximity to states without parental involvement laws. This made it possible for minors to avoid the law altogether by crossing state lines. In Minnesota, the distance from out-of-state abortion facilities appears to have worked against mi-

This paper, submitted to the Journal July 17, 1989, was revised and accepted for publication October 10, 1990.

gration. Blum determined that "[i]n counterdistinction to the Massachusetts data, there is little evidence to indicate large numbers of Minnesota youths are leaving the state for abortion (data available on request to author)."[2] It cannot be assumed that findings characterized by one set of background factors, such as proximity to out-of-state abortion facilities, will generalize to other settings.

In this study, the statewide impact of the Minnesota Parental Notification Law upon the incidence rate of abortion and birth, as well as upon the ratio of abortions to births and the ratio of early to late abortions, is examined.

Methods

Data

Abortion and birth incidence data were provided by the Minnesota Center for Health Statistics (MCHS). The data exclude all observations of unknown age and are restricted to residents of Minnesota. Live births to Minnesota residents are included regardless of whether the birth occurred inside or outside of Minnesota. Induced abortions reflect only those occurring in Minnesota.

Population estimates by age and gender are provided by the Minnesota Center for Health Statistics that computed them using a modified version of the cohort-component method for all years following the 1980 census.[7]

Throughout this report "birth(s)" and "abortion(s)" will refer to live birth(s) and induced abortions(s), respectively.

Outcome Measurements

The report utilizes six outcome measurements: four rates and two ratios.

- The abortion rate, the late abortion rate (>12 weeks), the early abortion rate (≤12 weeks) and the birth rate refer to the number of reported abortions (or births) in one year divided by the population estimate of females, in thousands, for that same year.
- The abortion-to-birth ratio refers to the number of abortions in a year divided by the number of births. Alternatively, this may be thought of as the abortion rate divided by the birth rate for a given year.
- The late-to-early abortion ratio refers to the number of late abortions in a year divided by the number of early abortions. Again, this may be thought of as the late abortion rate divided by the early abortion rate for a given year.

Measures of Effect

Each rate and ratio was examined using a linear model.[8,9] Serving as a dependent variable, the rate (or ratio) was modeled as a function of age category (≤17, 18–19 or 20–44 years old), the year of occurrence (1975 through 1987), and the age by year interaction.

First, each model was employed to determine whether a given rate (or ratio) three years before and four years after enactment of the Minnesota Parental Notification Law differed within each age category. Because the modeling was performed in the log scale, the pre-enactment (1978 to 1980) and post-enactment (1982 to 1985) values represent the geometric mean of the individual values comprising the pre-enactment and post-enactment periods. (The antilog of the arithmetic mean of log values corresponds to the geometric mean of the same measurement in the original scale. That is, anti-ln $[\ln a + \ln b]/2 = \sqrt{[ab]}$.)

Second, three additional contrasts were constructed to detect the presence of any age group by time interaction that might exist for a given rate or ratio. These contrasts reflect whether the pre-enactment to post-enactment *change* was different among minors than among 18–19 year-olds, or 20–44 year-olds, or among 18–19 year-olds than women 20–44 years old. It was assumed that a change due to the law, rather than to general factors operating in all age groups, would be most pronounced among women 17 years of age or younger; less evident among 18 and 19 year-old women who would have recently been, but would not presently be under the law (pregnancy at age 17 may mean birth at age 18); and least present among older women not subject to the law for at least two years.

Models

The mechanics underlying the linear models[8,9] used to construct the six contrasts described above were as follows. The model parameters, representing age category (two parameters capturing three age classifications), year (12 parameters capturing 13 years), and the age by year interaction (24 parameters reflecting the cross-product of age and year), were regressed against the ***natural log*** of the rate or ratio under question. Rows of each model's design matrix were combined to form the six contrasts. When the abortion rate, late abortion rate, early abortion rate, or birth rate served as the dependent variable, weighted least squares estimates and asymptotic variances for the estimates were obtained. When the abortion-to-birth ratio or late-to-early abortion ratio served as the dependent variable, maximum likelihood was used to obtain estimates and asymptotic variances. PROC CATMOD of Version 6.03 of the Statistical Analysis Software (SAS)[10] was employed to fit the models.

For ease of interpretation, the authors elected to display each contrast effect as a quotient (contrast ratio) in the original scale rather than a difference in the log scale. For any given contrast, this means that rather than presenting in tables the difference between two natural log values, it is the antilog of this difference that has been presented. It is evident that the difference between two identical log values will be "zero" while the corresponding contrast ratio will be unity (one). That is, $(\ln A) - (\ln A) = 0$ implies that the antilog is unity. Thus, contrast ratios equal to unity imply equivalence between the contrasted values.

Results

Table 1 contains the outcome measures examined in this study. For each outcome measure, Table 2 contains the contrast ratios that compare the pre-enactment and post-enactment periods. Contrast ratios greater than unity imply an increase in the outcome measure (abortion rate, birth rate, etc.) after enactment of the law and contrast ratios less than unity imply a decrease. Similarly, Table 3 contains ratios that reflect the age by time interactions. Here, a contrast ratio less than unity indicates a greater pre-enactment to post-enactment decline in the younger age group of the two being compared; a contrast ratio greater than unity indicates a greater increase.

Abortion Rate

Deviations from unity for the contrast ratios that compare pre-enactment and post-enactment periods (Table 2) are substantial in all age groups. Whereas the yearly abortion rates after the law's enactment increased for women 20–44 years old (who were substantially removed from its impact), abortion rates declined in both 15–17 and 18–19 year-olds during this same period. The pre-enactment to post-enactment decline was substantially greater for 15–17 than 18–19 year-old women, and for 18–19 year-old women than 20–44 year-old women (Table 3).

*Raw data provided by the Minnesota Center for Health Statistics.

†Abortion, birth, early abortion and late abortion rates are expressed as the number of abortions or births per 1000 women.

NOTE: Early abortions: ≤12 weeks; Late abortions: >12 weeks.

Birth Rate

Birth rates decreased in all age categories following enactment of the law (Table 2). However, the decline was most pronounced in 15–17 and 18–19 year-old women. Table 3 reveals that the pre-enactment to post-enactment change among 15–17 and 18–19 year-old women was similar, with both age groups evidencing a substantially greater decline than found among women ages 20–44.

Ratio of Abortions to Births

A marked drop in the abortion-to-birth ratio occurred after the law in 15–17 year-old women when compared to both 18–19 year-old women and 20–44 year-old women (see Tables 2 and 3). In Figure 1, the abortion rate and birth rate are plotted separately for 15–17 year-old women along with the abortion-to-birth ratio (abortion rate/birth rate) in order to examine the relative importance of abortions and births to the markedly declining abortion-to-birth ratio in this age group. It is evident that birth rates continue a modest and nearly linear decline, apparently unaffected by the law ($r = -0.89$ between birth rate and year). On the other hand, the abortion rate falls dramatically after the enactment of the law in August 1981. Together, these facts indicate that the drop in the 15–17 year-old abortion-to-birth ratio is due to a disproportionately greater decrease in the abortion rate (numerator).

Early and Late Abortions

The early abortion rate closely tracks the overall abortion rate (Tables 2 and 3). The pre-enactment to post-enactment late abortion rate substantially declines for women of 15–17 years, increases for women of 20–44 years, and remains nearly constant for women of 18–19 years (Table 2). The pre-enactment to post-enactment change in the late abortion rate, when compared between age groups, evidences a greater decline in late abortions for 15–17 than for either 18–19 or 20–44 year-old women (Table 3).

The late-to-early abortion ratio increased after the enactment of the law in all age groups (Table 2). However, the increase was greater among 15–17 year-old women than 20–44 year-old women (Table 3). Figure 2 reveals that a steep decline in early abortions, not an increase in late abortions, accounts for the increased late-to-early abortion ratio in 15–17 year-old women.

Discussion

Data presented in this study are compatible with the hypothesis that, initially, parental notification facilitated pregnancy avoidance in 15–17 year-old Minnesota women. Abortion rates fell markedly in this age group relative to older women. Birth rates also fell, but only in keeping with a long-term trend established before enactment of the law. One possibility is that when minor women are restricted from abortion without notifying parents or seeking court approval, and are geographically prohibited from easy access to out-of-state abortions,[2] they are more likely to take measures to avoid pregnancy.

Although the data are compatible with this hypothesis, other explanations are possible. For example, a growing concern over human immunodeficiency virus infection, and/or awareness and availability of birth control may explain in part or in full these findings. However, the abrupt nature of the change in abortion rate, a phenomenon found also in Massachusetts by Cartoof and Klerman,[1] makes these rival hypotheses less tenable. In any event, the data argue against Clary's[3] concern that more minors might carry pregnancies to term as an indirect effect of the parental notification law. If such were the case, it seems unlikely that birth rates would have continued to decline in 15–17 year-olds along the linear trend line established prior to the law, or that the decline in birth rates would be nearly identical between 15–17 and 18–19 year-old women.

The pre-enactment to post-enactment increase in the proportion of late (>12 weeks) to early (≤12 weeks) abortions was greater for 15–17 than for 20–44 year-old women. At least two hypotheses may explain this finding. First, the law may have been more successful in preventing pregnancy among minors who would have had early abortions than among minors who would have had late abortions. A second possibility is that the law caused delays for a greater percentage of a declining number of minors seeking abortions. Regardless, the claim that the law caused more minors to obtain late abortions is unsubstantiated. In fact, the reverse is true. For ages 15–17 the number of late abortions per 1,000 women decreased following the enactment of the law. Therefore, an increased medical hazard due to a rising number of late abortions was not realized.

In this paper no effort has been made to confront the philosophical and legal issues surrounding parental involvement laws. Rather, the authors have pursued a limited task, that of empirical evaluation within a framework of defined outcome parameters. This study is consistent with the hypothesis that conception among minor women may be reduced immediately following enactment of parental notification legislation when migratory abortion across state lines is not a viable alternative. However, generalizations to other states must be made cautiously, as Minnesota is a unique state with a low minority population and a low pregnancy rate even before the parental notice legislation. The authors emphasize that replication in states other than Minnesota will be required to sustain the hypothesis. ☐

TABLE 2—Contrasts Between Pre- and Post-Enactment Periods[*]

Outcome Measures	Age (years)	Pre-Enactment[**]	Post-Enactment[†]	Contrast Ratio (Post/Pre) With 95% CI
Abortion Rate[††]	15–17	19.012	13.635	0.717 (0.692, 0.743)
	18–19	38.181	34.638	0.907 (0.883, 0.932)
	20–44	13.280	13.931	1.049 (1.034, 1.064)
Birth Rate[††]	15–17	17.663	15.510	0.878 (0.848, 0.909)
	18–19	57.338	50.213	0.876 (0.857, 0.895)
	20–44	77.982	76.191	0.977 (0.971, 0.983)
Abortions/Births	15–17	1.076	0.879	0.817 (0.777, 0.859)
	18–19	0.666	0.690	1.036 (1.000, 1.074)
	20–44	0.170	0.183	1.074 (1.057, 1.091)
Early Abortion Rate[††]	15–17	15.343	10.507	0.685 (0.658, 0.713)
	18–19	32.413	28.749	0.887 (0.861, 0.914)
	20–44	12.032	12.554	1.043 (1.027, 1.059)
Late Abortion Rate[††]	15–17	3.653	3.114	0.852 (0.788, 0.921)
	18–19	5.750	5.867	1.020 (0.952, 1.093)
	20–44	1.247	1.375	1.103 (1.052, 1.157)
Late/Early Abortions	15–17	0.238	0.296	1.245 (1.140, 1.359)
	18–19	0.177	0.204	1.150 (1.067, 1.241)
	20–44	0.104	0.110	1.058 (1.006, 1.112)

Psychosocial Factors in Maternal Phenylketonuria: Prevention of Unplanned Pregnancies

Susan E. Waisbren, PhD, Shoshana Shiloh, PhD, Paula St. James, MA, and Harvey L. Levy, MD

ABSTRACT

Background. Women with phenylketonuria (PKU) not treated prior to conception can have a pregnancy that results in serious fetal damage. In this report, factors associated with preventing unplanned (and hence late treated) pregnancies are described.

Methods. Subjects included 60 phenylketonuric women and two comparison groups composed of female acquaintances and diabetic women. All were interviewed and administered tests of intelligence, general well-being, knowledge, and personality.

Results. Thirty-five percent of the sexually active women with PKU used contraception only sporadically. The variables that best predicted reported frequency of birth control use were the extent to which women felt social support to use contraception ($r = .64$) along with positive attitudes about birth control ($r = .66$) and knowledge of family planning ($r = .43$). For the comparison groups, a different pattern of variables predicted contraceptive use, with locus of control figuring most prominently for the diabetics ($r = .39$) and social support for birth control being most important for the acquaintances ($r = .46$).

Conclusions. As more girls with PKU enter childbearing ages, there will be an increased need for specific programs that address psychosocial factors in maternal PKU. (*Am J Public Health* 1991;81:299–304)

Introduction

Maternal phenylketonuria (PKU) as a cause of mental retardation and birth defects is a new phenomenon. In the past, most young women with PKU (an inborn error of phenylalanine metabolism) were mentally retarded and few bore children. Now, most such women are mentally normal, having been born since newborn screening was initiated in the 1960s and treated from early infancy with a phenylalanine-restricted diet.[1] In the United States there may be as many as 4,000 women of childbearing age with PKU,[2] the majority of whom are at risk for pregnancies that can result in abnormal children. For those with the most severe and most common form of PKU, the frequencies of complications in offspring from untreated pregnancies are 92 percent for mental retardation, 73 percent for microcephaly, 12 percent for congenital heart disease, and 40 percent for low birth weight.[3] In fact, it is feared that in the next generation, the consequences of maternal PKU could replace the number of individuals with PKU in whom mental retardation has been prevented by newborn screening.[4, 5]

Dietary treatment will protect the fetus but only under the proper circumstances. Treatment begun prior to conception and continuing throughout pregnancy appears to offer maximum protection, whereas treatment even in the first trimester may not prevent some of the adverse effects of maternal PKU.[6,7] Since many young women with PKU discontinued the special diet during childhood,[8] the strategy for preventing birth defects from maternal PKU must include careful family planning so that diet can be initiated before conception.

Tracking adolescents and young adult women with PKU so that they can be advised of the high risk to their pregnancies and the possibilities of treatment is difficult, but with much effort can be done.[2] In Quebec, there is a registry that tracks individuals with PKU through adulthood.[9] The results of other tracking efforts, however, indicate that women with PKU usually seek treatment after they are pregnant rather than before.[7,10,11] The reasons for this are unknown.

The overall purpose of our study is to identify these reasons. We will describe how women with PKU face questions of sexuality and childbearing in order to determine the factors related to preventing unplanned pregnancies in maternal PKU.

We describe here the findings from the initial interviews of all subjects who were not planning a pregnancy and were not pregnant when the study began in 1985.

Methods

Subjects

Young women in New England known to have hyperphenylalaninemia, ages 16 to 35 years, were invited to participate in a five-year longitudinal study.

FIGURE 1—A Stage Model for Maternal PKU

Women with moderate or severe mental retardation were excluded from the sample. Recruiting from clinic lists, newborn screening records, and public health registries, we contacted all women with PKU who met the inclusion criteria regarding age and intellectual functioning. We developed two comparison groups—one consisting of age-matched female acquaintances recruited among those whose names were supplied by the subjects and the other consisting of young women with diabetes, who share childbearing risks and the need for medical intervention prior to and during pregnancy with PKU women.[12,13] Each diabetic woman, who had been diagnosed for at least one year and had no major medical complications, was individually matched to a PKU subject for age, and whenever possible, for level of education and marital status.

Two hundred and sixty-two women satisfied the criteria for inclusion in the longitudinal study, and 205 agreed to participate. These included 94 percent of the eligible women with PKU, 74 percent of the acquaintances, and 62 percent of eligible diabetics. Among the 205 who participated, 186 were sexually inactive or sexually active but not desiring pregnancy and were enrolled in the phase of the study concerned with preventing pregnancy. These 186 consisted of 60 with PKU, 65 acquaintances, and 61 with diabetes.

Among the 60 subjects with PKU, 53 have the more severe biochemical defects (classic or atypical PKU) that will require resumption of treatment prior to pregnancy.[3] Seven of the subjects have mild hyperphenylalaninemia, a less severe biochemical defect often left untreated during childhood. Because it is unclear whether mild hyperphenylalaninemia requires dietary treatment during pregnancy,[14,15] these women were included in the PKU group.

Most subjects with PKU had received a written brochure about maternal PKU and had been invited to maternal PKU education groups. Thirty-eight women had attended at least one group. However, the majority had not attended a PKU clinic within the year prior to the study. As a rule, the women had been advised to plan their pregnancies, begin diet, and reduce blood phenylalanine levels before discontinuing contraception. A few had been advised not to have children and to plan on adoption or to wait until more was known about maternal PKU.

Fifty-eight of the 61 women with diabetes (95 percent) are insulin dependent (Type I), while the other three have been treated only with diet (Type II).

Variables and Procedures

Variables for this study were derived from a psychosocial model we developed to describe the challenges faced by women with PKU during various stages in the maternal PKU life-cycle[16] (see figure 1). These variables were selected from a variety of theoretical approaches and covered background issues, personality, knowledge, attitudes and beliefs, and social support. We chose our initial battery after first developing a list of hypotheses regarding prevention of unplanned pregnancy in maternal PKU. This initial battery was piloted extensively among teenagers and women with no known medical conditions, women with diabetes, and older women with PKU.

The dependent (outcome) variables for those women who reported having had sexual intercourse (the sexually active group) were frequency of birth-control use, extent of social activities, and a general quality-of-life score. Frequency of birth-control use refers to the regularity with which a woman reported using any contraceptive method. She indicated this by selecting the frequency of use, on a one to seven scale, ranging from "never" to "all the time." The type of birth control method was related to frequency, with oral contraceptives generally being used "all the time" and all other methods being used less often. Hence, for data analysis purposes, the "frequency" rather than "type" of birth control was selected.

The second outcome variable, extent of social activities, measures the types of activities the woman listed that involve social interactions, such as membership in clubs, participation in religious groups, sports, dating, and parties. This variable was selected to determine if women with PKU avoided certain social situations, perhaps due to anxiety about maternal PKU.

The third outcome variable, the General Health Rating Index (GHRI),[17] measures the degree to which people worry about their health, experience pain, or alter their life-style for health reasons. These topics were also explored in open-ended questions. The responses to the open-ended questions were categorized according to whether the answer was neutral, positive, negative, or a combination of these. All ratings were double-scored, and reliability was greater than 95 percent.

For women who reported never having had sexual intercourse (the sexually inactive group), the social activities scores and the GHRI were the outcome measures.

The independent variables included demographic factors, level of intelligence, knowledge about family planning, knowledge about maternal PKU, personality characteristics, social support for family planning, and attitudes and beliefs about contraception, sex, and childbearing.

The interview consisted of introductory questions that provided demographic information. Socioeconomic status was determined using the Hollingshead-Redlich Two Factor Index of Social Position, based on education and job title.[18] Intelligence was measured by the Wechsler Adult Intelligence Scale-Revised (WAIS-R)[19] or the four-subtest short form of the WAIS-R,[20] when a full-scale score was not available from clinic records.

A test of fertility and contraception knowledge, adapted from Kempton and Forman[21] and a test of knowledge about

maternal PKU[22] (and a comparable test for women with diabetes) were devised for this study. These tests gave one point for a correct response, with 13 possible points for the contraception knowledge test and ten points for the knowledge of maternal PKU and diabetes tests.

Personality was measured by the Adult Nowicki-Strickland Internal-External Locus of Control Scale[23] and the Rosenberg Self-Esteem Scale.[24]

Social support for birth control was determined, as suggested by Fishbein[25] and Vinokur-Kaplan,[26] by asking subjects to name the three people to whom they felt closest and then to rate on a seven-point scale the degree to which each of these people would support their using birth control. The mean ratings constituted the score for social support for birth control.

Attitudes and beliefs were defined by a series of statements to which subjects indicated the extent of their agreement on seven-point scales. These statements, adapted from published studies, were about sexual activity, use of birth control, attitudes regarding contraception, and past pregnancies.[27,28] A composite "attitude towards birth control" score was developed from responses to three questions regarding the benefits, advisability, and comfort in using and procuring contraception.

Each woman in the study was interviewed either in her home or at the hospital. All written questionnaires required no more than a sixth-grade reading level. To increase the comfort of the subjects (and to ensure confidentiality), response cards for personal questions concerning sexual activity, birth control, and pregnancy were provided. Each session lasted about two hours.

Data collection also included review of medical records for information on diagnosis and treatment of PKU or diabetes.

Data were analyzed utilizing the Statistical Package for the Social Sciences (SPSS).[29] To determine differences between the study groups, chi-square or one-way analyses of variance (with Scheffé tests for pairwise comparisons) were used. Pearson correlations were used to identify variables related to successful achievement of outcome goals.

Consent procedures standardized by the Children's Hospital (Boston) Committee on Clinical Investigations were followed.

Results

Characteristics of the Sample

Demographic and other background characteristics of the three groups are listed in Table 1. The groups are similar in age, with a mean of approximately 21 years at the time of the study. The frequencies of those who had been pregnant or had a child were less among the women with PKU. Women with PKU were more likely to live with their parents, were less likely to have a driver's license, had fewer years of education, and had a lower mean IQ. Six women with PKU and one acquaintance (but none with diabetes) performed in the range of mild mental retardation, with scores between 60 and 67.

Prevention of Unplanned Pregnancies

As noted in Table 2, 43 percent of the women in the PKU group reported that they were currently or had been sexually active, a smaller proportion than those in the other groups. Among PKU women who had had sexual relations, 19 percent never used birth control, and 65 percent reported always using birth control when they had sexual relations. These findings, along with the type of contraception selected, were similar to those of the comparison groups. As noted in Table 3, married women with PKU were more likely to always use birth control, while unmarried women were less consistent in this respect.

Women with PKU who reported never having had sexual intercourse and those who were sexually active were similar in age, with mean ages of 20.6 and 20.9 years respectively. Less than 13 percent of both groups indicated disapproval of premarital sex and birth control.

The seven women with mild hyperphenylalaninemia did not differ from other women with PKU in terms of the demographic or psychological variables studied, except that they had a more internal locus of control (F = 9.3, SE = .39). All but two lived with their parents. Their ages ranged from 16 to 22, and their IQ ranged from 78 to 117. Five had had sexual intercourse, among whom two relied on

Percent reporting alterations in plans to have children	42.3	55.9

the use of condoms intermittently and three used oral contraception.

Factors Associated with Prevention of Unplanned Pregnancy

As noted in Table 4, the degree of social support for birth control that PKU women received from individuals in their social network and their own attitudes about birth control, including comfort in discussing birth control with a health care provider, were critical factors for contraceptive behavior, correlating .64 and .66 respectively with frequency of contraceptive use. In addition, knowledge of family planning, but not knowledge of maternal PKU, correlated with frequency of contraceptive use. Among women with PKU, personality variables, age, marital status, living situation, IQ, and social class were unrelated to contraceptive use. Multiple regression analyses indicated that when the variable for either social support for birth control or the attitudes about birth control was entered first in the equation, no other variables were significant.

A different pattern of variables predicted contraceptive use for the comparison groups, with only locus of control figuring prominently for the diabetics and only social support for birth control being important for the acquaintances.

Compared with their acquaintances and women with diabetes, women with PKU attained lower scores on the Knowledge of Family Planning Test (F = 7.8 SE = .14) and had a more external locus of control (F = 9.3 SE = .4).

Quality of Life

As noted in Table 5, for women with PKU, the scores on the GHRI were comparable for those who were sexually active and those who were not. In general, they were involved in similar types of spare-time pursuits, although the women who reported never having had sexual relations were somewhat more likely to engage in social activities. Few of the sexually active or sexually inactive women reported alterations in their social lives because of PKU. Women with PKU who identified negative effects from their disease reported having fewer friends, fewer activities, difficulties explaining their disease to boyfriends, and concerns about becoming sexually involved. More than half in each group reported alterations in their plans for the future due to PKU. Somewhat more of the sexually inactive women mentioned concerns about maternal PKU, and equal numbers mentioned reduced career opportunities as a consequence of PKU-related learning disabilities. Nonetheless, compared with women with diabetes, women with PKU attained significantly higher scores on the GHRI (F = 16.5 SE = 1.5), indicating less worry, less pain, and less of a negative impact from their disease. Fifty percent of women with PKU, compared with 85 percent of women with diabetes, reported undesirable alterations in their social activities and plans for the future as a consequence of their disease.

Discussion

Until now studies of individuals with PKU have focused on intellectual and academic development. However, the necessity for treatment prior to pregnancy in maternal PKU stimulated us to investigate other aspects of development. In this study, we concentrated on those psychosocial factors in young women with PKU that we believe will be important in their meeting the challenges of family planning in maternal PKU.

We found that many young women with PKU tend to live with their parents and to be without a driver's license. Nonetheless, they are engaged in social activities and competitive employment. They plan to marry and bear children. It is unclear why fewer women with PKU reported having had sexual intercourse compared with their acquaintances and the diabetic women, who were similar in age and marital status. We believe, however, that over the next few years, more will become sexually active. Unfortunately, those who are sexually active seem to be at high risk for unplanned pregnancies, since 35 percent of them report only intermittent use of birth control.

It appears that social support for birth control and positive attitudes about contraception each have a very significant influence on the reported contraceptive behavior of young women with PKU. These findings are consistent with Fishbein's theory of reasoned action, which states that attitudes, social norms, and the willingness to comply with these norms are predictors of behavior.[30-32]

With the exception of social support, those factors that correlate with birth control use in women with PKU are specific to them and unlike correlating factors in the two comparison groups studied. For instance, their external locus of control does not predict contraceptive frequency; yet in the diabetic subjects and in published studies, an external locus of control is associated with infrequent contraceptive use.[33-34] On the other hand, knowledge of family planning is significantly correlated with reported frequency of birth control use only in the PKU women. Their knowledge of family planning, in general, is lower than that of the other subjects studied and, in many instances, may be sufficiently low to impair their ability to choose and use contraceptive measures. Education programs such as those described by Cohen and his colleagues in Israel[35] may be beneficial to these women. In developing our test of knowledge of maternal PKU, we found that knowledge scores were higher among the 38 women who had attended a PKU education group than among the 22 who had not done so.[22] Finally, although the women with PKU have attitudes about birth control that are comparable to those of their acquaintances and the diabetic women, their contraceptive behavior appears to be more highly influenced by their attitudes. Further analyses show that although IQ is significantly related to knowledge of family planning and knowledge of maternal PKU, it is not significantly related to the frequency of contraceptive use.

In addition to these findings, we gained a keener sense of how women with PKU approach the question of childbearing. The vast majority consider having children a natural sequel to finding a husband, and few acknowledge that an unplanned pregnancy might occur. In these attitudes, they are similar to adolescents confronting a variety of medical and health issues.[36]

We also learned more about the ways in which women with PKU related to health care providers. As a group, they were extraordinarily cooperative, perhaps reflecting a sense of trust developed over years of association with the PKU programs. Ninety-four percent of those contacted participated in the study. Despite this cooperation, only a few of the women made follow-up clinic appointments. This may be due to apprehension about the blood test and physical examination, to a belief that they already know enough about maternal PKU, or to a presumption that an unplanned pregnancy was not likely to occur.

Women with PKU were self-accepting, as indicated by their responses to the self-esteem questionnaire. Many expressed the thought that they "used to have" PKU when they were children on the special diet. For them, prevention of unplanned pregnancies may have been no different than it was for other teenagers and young adults striving for a sense of identity and independence. The risks to the fetus could easily be forgotten or ignored during this time of self-exploration. This may explain why birth control practices among those with PKU were no better than those of the acquaintances who did not face known childbearing risks. On the other hand, fewer women with PKU were sexually active, perhaps due to fears of unplanned pregnancies, to concerns regarding risks to the fetus, or to limited social opportunities. These speculations regarding the psychological impact of PKU will be explored further as the study continues. Social support will also receive more intensive examination in the continuing study. We plan to define social support more precisely in terms of the nature of support networks, the importance of peers versus family, the role of perceived as opposed to actual support provided, and the extent to which the concept reflects general support as compared with specific encouragement for birth control use.

As in any study dependent on self-report, the reliability and validity of the subjects' responses should be checked. We asked several duplicate questions, worded slightly differently, so that inconsistent answers about sexual activity and birth control use could be verified. Our sense was that the women were generally honest. Since this is a longitudinal study, each subject will be interviewed at least five times, and further checks can be made on the consistency and reliability of the results.

In the near future as more girls with PKU enter childbearing ages, the need for specific programs for maternal PKU, already serious, will dramatically increase. A critical first step is to develop a registry in the United States similar to that in Canada to track women with PKU so that information and services can be provided. Our society and its health care system must confront the issue of maternal PKU. To ignore the issue is to punish those who because of their inherited condition are at risk for bearing defective children. ☐

Conference of Public Health Laboratorians 1991 Kimble Methodology Award

The Kimble Methodology Award, sponsored by the Conference of Public Health Laboratorians and supported by Kimble Glass, Inc., Vineland, New Jersey is intended to recognize significant contributions to the development of diagnostic methodology for use in the public health or diagnostic laboratory. The 1990 Award winners were Dr. Robert E. Weaver and Ms. Dannie G. Hollis, Special Bacteriology Laboratory, Centers for Disease Control, Atlanta, Georgia, for their work on the characterization and identification of numerous genera and species of medically important bacteria.

Nominations are being sought for the 1991 Kimble Methodology Award, (the 40th annual award) to be presented at the annual meeting of the Conference of Public Health Laboratorians scheduled for November 10, 1991 in Atlanta, Georgia. The award consists of a $1,000 check and a plaque presented by Kimble Glass. In addition, travel and subsistence will be paid for the recipient to attend the 1991 Conference meeting.

The deadline for submission of nominations for the 1991 award is June 17, 1991. All nominations should be entered according to the following rules:

- Nominee's work should be a fundamental contribution, or an adaptation of such, to diagnostic methodology for use in the public health or diagnostic laboratory. Degree of acceptance and use of the methodology will be considered.
- Nominee(s), either an individual or two or more working together, must live and work on the North American continent.
- The nomination (10 copies) shall consist of a letter describing the reason for nomination; the recognition accorded the nominee for the work and the degree of acceptance by and/or its importance to the work of public health or diagnostic laboratories; the curriculum vitae of the nominee; the nominee's current place of employment; a list of the nominee's publications along with reprints of representative recent publications; and, optionally, letters of support for the nomination.

Send nominations to: Hilton T. Goulson, PhD, Kimble Award Chairperson, Department of Parasitology and Laboratory Practice, UNC School of Public Health, CB #7400, Chapel Hill, NC 27599-7400. Tel: (919) 966-3892.

Predicting Onset and Chronicity of Women's Problem Drinking: A Five-Year Longitudinal Analysis

ABSTRACT

Background. Longitudinal studies of adult drinking have typically excluded or sampled only small numbers of problem drinking women, and have measured a limited range of influences on women's drinking behavior.

Method. To study the development of women's problem drinking over time, five-year follow-up interviews were conducted with two groups of respondents from a 1981 national survey of women's drinking: 143 problem drinkers and 157 nonproblem drinkers. Regression analyses examined effects of 1981 predictors on six measures of 1986 problem drinking, for problem drinkers and nonproblem drinkers separately.

Results. Among 1981 nonproblem drinkers, predictors of onset of problem drinking indicators by 1986 included younger age, cohabiting, and lifetime use of drugs other than alcohol. The most consistent predictor of persistent (chronic) problem drinking was sexual dysfunction; other predictors included being employed part-time or never married, and experiencing recent depression. Divorce or separation predicted *lower* levels of subsequent alcohol dependence among problem drinkers.

Conclusions. Findings suggest that different personal and social factors predict the onset of problem drinking as compared with its continuation, and point to nontraditional life-style, sexual dysfunction, and role deprivation as potentially important variables. (*Am J Public Health* 1991;81:305–318)

Introduction

Longitudinal research on general population samples is essential for predicting the onset and chronicity of problem drinking, but has not been adequately applied to the study of women drinkers. A majority of the longitudinal studies in a recent comprehensive review[1] totally excluded female respondents. Of 12 longitudinal studies of adult drinking included in an international collaborative effort,* four have exclusively male samples, while only one focuses primarily on females.

Those longitudinal studies that do sample women frequently have insufficient numbers of heavy drinking and problem drinking women for multivariate analysis, due to the lower rates of heavy drinking and drinking-related problems among women than among men. Even a relatively large national probability sample of 2,000 respondents (half female) yields only 30 to 60 women who drink as heavily as 14 drinks per week.[2] One frequently cited longitudinal study[3] had only three women in its problem drinker sample. In addition, most longitudinal studies that include women have focused on immediate contexts and correlates of drinking behavior, with relatively little attention to other or longer term influences on women's drinking.

The five-year longitudinal study reported here gathered information about diverse antecedents and consequences of drinking and drinking problems in women. This paper addresses two major questions: 1) What factors predict the incidence (onset) of problem drinking among women over a five-year period? 2) What factors predict the chronicity—continuation or worsening—of women's problem drinking over five years? Because drinking may be reciprocally related to a number of personal and social-environmental conditions, we analyze drinking as both a predictor and an outcome of these conditions.

Methods

Sampling

The data are from a national survey of women's drinking conducted in the fall and winter of 1981 and from a follow-up survey in the fall and winter of 1986. Sampling and fieldwork for both surveys were conducted by the National Opinion Research Center (NORC).

The 1981 survey interviewed a stratified probability sample of the noninstitutionalized US population age 21 and over, obtained from initial screening of 4,032 households. After 10-minute screening interviews to determine women's drinking levels, NORC interviewers requested interviews from every moderate-to-heavy drinking woman (four or more drinks per

This paper, submitted to the Journal December 8, 1989, was revised and accepted for publication August 6, 1990.

week), from every woman reporting a history of drinking-related problems, and from one of every four lighter drinking or abstaining women. Interviews were completed with 500 moderate-to-heavy drinking women and 39 women who were self-reported former problem drinkers (89 percent completion rate), and with 378 lighter drinking and abstaining women (83 percent completion rate). A probability sample of 396 men (66 percent completion rate) was also interviewed as a comparison group. Detailed information about sample design, statistical weighting, and comparisons with other national data are provided elsewhere.[2,4]

The 1986 follow-up survey compared two subsamples of female respondents. Problem Drinkers (PDs) were women who in 1981 had reported at least two of the following: 1) average consumption of one or more ounces of ethanol per day; 2) one or more drinking-related problems in the past 12 months; and 3) one or more alcohol dependence symptoms in the past 12 months. These problem drinking criteria are similar to those used in other studies,[5-7] and the proportion of women thus identified—10.1 percent of the total weighted female sample—falls in the middle of the range of estimates of problem drinking rates among women in US surveys during the 1960s and 1970s (1 percent to 21 percent).[6] Nonproblem Drinkers (NPDs) were women who in 1981 drank more than one drink per month but reported none of the three problem drinking indicators.

Application of these criteria produced samples of 178 PDs and 199 NPDs. Of these, 157 PDs (88.2 percent) and 185 NPDs (93.0 percent) were successfully located by NORC staff. Six percent of the total follow-up sample (five PDs and 16 NPDs) were deceased, too ill or senile to be interviewed, or out of the country. Of the remaining respondents potentially available for interviews, interviews were completed with 143 PDs (94.1 percent) and 157 NPDs (92.9 percent). The final sample thus represents 80.3 percent (143 of 178) of all PD cases in the 1981 sample and 78.9 percent (157 of 199) of all 1981 NPDs. (Not included in the follow-up sample were 290 women who abstained at least 30 days before the 1981 survey, 110 infrequent drinkers who drank one drink per month or less in the 12 months preceding the survey, and 140 women who drank more than one drink per month and who reported only one of the three problem drinking indicators.)

In order to assess possible selection bias due to attrition, nonresponse rates (combining refusals and locating failures) were examined for respondent categories based on all major drinking variables, seven major demographic variables, and two sexuality variables (nontraditional sexual behavior and sexual dysfunction), within PD and NPD subsamples separately. Nonresponse rates for the following categories exceeded the overall subsample nonresponse rates by 15 percent or more: Black PDs; NPDs age 71 and older; PDs separated from their husbands; PDs with household income under $8,000; NPDs with household income $8,000–$15,000; NPDs completing college but not graduate school; NPDs who were retired or disabled; and NPDs reporting both masturbation and premarital sexual experience. None of the drinking variables had categories with excessive nonresponse rates. Based on their known or expected relationships to other variables, income and race seemed to be the two most important variables for weighting adjustments. Accordingly, nonresponse weighting adjustments were applied to the 1986 sample based on division of the PD and NPD subsamples into three categories: Blacks; race Other/income under $15,000; race Other/income $15,000 and above.

Data Collection

The 1981 survey questionnaire was administered face-to-face by female NORC interviewers. It included questions (described below) about drinking behavior, drinking-related problems, alcohol dependence symptoms, and lifetime drinking history. Other questions dealt with demographic characteristics, family history and socialization, personality traits and values, social roles, characteristics of the respondent's primary interpersonal relationship, stressful life events, depression, sexual experience, reproductive dysfunction, use of drugs other than alcohol, and antisocial behavior.

The follow-up survey, again administered by female NORC interviewers, used measures of drinking behavior and drinking consequences identical to those used in 1981. Other questions asked about changes in demographic characteristics such as marital and employment status since 1981, and about other major life events such as births, deaths, physical illness, depression, and sexual and reproductive dysfunction. New questions addressed employment experiences, feelings of role overload and role deprivation, sexual experience and sexual abuse, and relationship conflict/violence.

Measures

Predictor Variables: The 1981 survey was designed to assess the individual and combined effects of a large number of variables that had been associated with women's drinking in previous theory and research, as well as additional variables not addressed in earlier work. The conceptual model guiding the study assumed that a woman's demographic and family background (including such variables as age, education, religious orientation, and recalled parental behavior including drinking) affects three major sets of influences on drinking behavior: 1) personality characteristics (including personal motives and values, drinking-related beliefs and attitudes, and gender-role attributes); 2) perceived social environment (including social norms and interactions with significant others); and 3) life experiences (including stressful life events, sexual and reproductive experience, affective disorder, other drug use, and antisocial behavior). Background, personality, social environment, and life experiences all influence contexts of drinking behavior, levels of alcohol consumption, and drinking consequences.[8] From the large set of variables initially included in the 1981 survey, variables were selected for the present longitudinal analyses if they had shown a significant positive relationship to heavier drinking and/or to adverse consequences of drinking in earlier cross-sectional analyses of 1981 data.[2,4,8-13]

Time 1 predictors were demographic characteristics, personality attributes, social-environmental conditions, and life-history events as measured in the 1981 survey. For some variables, additional interim predictors consisted of specific changes in demographic status (e.g., becoming divorced or unemployed) or major life experiences (e.g., miscarriage/stillbirth, depressive episode) during the 1981–86 follow-up interval. We also measured the Time 2 (1986) values of Time 1 predictors in order to analyze possible Time 2 consequences of Time 1 drinking. Brief descriptions of personality variables, sexuality-related variables, and drinking variables are provided in the Appendix; descriptions of all other variables can be obtained by writing the authors.

Drinking Variables: Questions about the frequency and quantity of consumption of wine, beer, and liquor were used to estimate respondents' average daily intake in ounces of ethanol per day for the 30 days preceding the survey.[5,14] Minor refinements in the 1986 survey adjusted for

TABLE 1—Changes in Problem Drinking Indicators, 1981–86, among 1981 Nonproblem Drinkers (NPDs) and Problem Drinkers (PDs), by Age (%)

1986 Problem Drinking Indicators	Age 21–34		Age 35–49		Age 50+		Total	
	NPDs	PDs	NPDs	PDs	NPDs	PDs	NPDs	PDs
None	73.0	37.8	95.6	25.8	95.4	26.1	88.8	32.7

Weighted N	(46)	(80)	(58)	(37)	(49)	(23)	(153)	(140)

the new popularity of wine coolers and low-alcohol beer, the use of malt liquor, and slight declines in the ethanol content of wine and liquor. Estimating procedures are summarized in the Appendix. Other drinking measures included the frequency of heavy episodic drinking (six or more drinks per day) and the frequency of intoxication ("feeling drunk") in the 12 months preceding the survey.

An index of nine kinds of problem consequences of drinking included driving while feeling intoxicated, starting fights (with family members or others), damage to job performance, interference with housework or chores, drinking-related home accidents and problems with children, and spouse's or partner's complaints about the respondent's drinking and threats to leave the drinker. An index of five alcohol dependence symptoms consisted of memory lapses while drinking (blackouts), rapid drinking, morning drinking, inability to stop drinking before becoming intoxicated, and inability to stop or reduce alcohol consumption over time. These indexes summed the number of different consequences and symptoms reported for the 12 months preceding the survey. A composite Problem Drinking Index (PDI) summed the occurrence in the past 12 months of 1) any episode of intoxication, 2) any problem consequence, and 3) any alcohol dependence symptom (scores ranged from zero to three).

Data Analysis

Data analysis involved weighting cases to take into account unequal probabilities of inclusion at several levels of selection, including 1981 stratification by drinking level, 1986 selection of PD and NPD samples, and response rate variations in both surveys.[4] For significance tests we adjusted weights by constant ratios to produce weighted Ns equal to the actual numbers of respondents in the PD and NPD samples.

This paper reports results of three analyses. First, cross-tabulations describe patterns of change in problem drinking indicators between the 1981 and 1986 surveys. Second, regression analyses examine the effects of individual Time 1 and interim predictors on six Time 2 drinking variables, and the effects of six Time 1 drinking variables on Time 2 values of Time 1 predictors. Dependent variables in the regression analyses were standardized residuals. Each Time 2 drinking variable was regressed on its Time 1 equivalent plus measures of 1981 consumption (average consumption and heavy episodic drinking) to produce standardized residuals as measures of Time 2 drinking patterns not predicted by Time 1 drinking patterns. Similarly, each Time 2 condition (e.g., sexual dysfunction in 1986) was regressed on its Time 1 equivalent, producing standardized residuals as measures of Time 2 conditions not accounted for by Time 1 conditions.

The third analysis uses results of the second analysis as a winnowing procedure to develop 12 unique multiple regression equations showing the combined effects of Time 1 and interim predictors on the same standardized residuals of each of six measures of Time 2 drinking, for the NPD and PD samples separately. Predictors were included in these equations 1) if they predicted ($p < .10$) the Time 2 drinking variable in the bivariate analyses described above, or 2) if they predicted ($p < .10$) the Time 2 drinking variable in (a) equations that entered all Time 1 predictors simultaneously, or (b) equations that entered all predictors simultaneously, using interim predictors for those variables with both Time 1 and interim versions. Every equation included age as a control variable. In the 12 final equations, predictors were entered hierarchically in two steps: Time 1 predictors (those that occurred before 1981 or that constituted the respondent's status in 1981), followed by interim predictors (occurring during the follow-up interval). Based on earlier cross-sectional findings, every predictor (except age) in the second and third analyses was hypothesized to predict heavier drinking or more adverse drinking consequences. For this reason, one-tailed tests of significance were used for relationships in the predicted direction, two-tailed tests for relationships in the opposite direction.

Design effects were assessed for seven of the resulting regression equations.[15] In only two (intoxication and PDI, among PDs only) did the mean of the individual square roots of design effects slightly exceed 1.0 (1.017 and 1.101 respectively), and the overall mean for all predictors in the seven equations was less than 1.0 (0.963). This indicates that the findings reported here are not affected by weighting or cluster characteristics of the PD and NPD subsamples to an extent that would require adjustment for departures from the simple random sampling model.

Results

Changes in Problem Drinking

Table 1 shows five-year changes in the three problem drinking indicators (consumption, problems, symptoms) used to define the 1981 NPD and PD samples. A large majority of all 1981 NPDs remained free of problems five years later; 11.2 percent had developed at least one problem drinking indicator. Of the 1981 PDs (who in 1981 had reported at least two of the three indicators), approximately one-third (32.7 percent) by 1986 reported none of the three indicators and another one-third (30.7 percent) reported only one indicator.

Patterns of change were quite different for three age groups:

- Onset of problem drinking was most common among young women age 21–34; more than one-fourth (27.1 percent) of the 1981 NPDs in this age group reported at least one problem drinking indicator by 1986, compared with 4.4 percent of 1981 NPDs age 35–49 ($\chi^2 = 8.85$,

*Not analyzed as a dependent variable.

Note.–Time 2 drinking variables were standardized residuals from regressing 1986 drinking variables on their 1981 equivalents. Each column shows multiple regression results for predictors of onset and chronicity of a specific Time 2 drinking variable. Predictors from the same equation appear in Tables 2 (sociodemographic), 3 (personality/life experience), and 4 (interim predictors). Beta 1 coefficients are from the first hierarchical step (including only Time 1 predictors) and Beta 2 coefficients are from the second hierarchical step (adding interim predictors). Underlined betas are significant at $p<.05$. With the exception of the far right-hand column (Problem Drinker Sample Criteria were not analyzed as a dependent variable), the absence of beta values indicates that the predictor was not significantly associated with that drinking variable in preliminary bivariate and multivariate winnowing analyses, and thus was not included in the final hierarchical equation. Weighted means and percentages are provided to illustrate the fit, or contrast, of simple bivariate comparisons with the more rigorous and conservative multiple regression analyses. Although means and rates are weighted, Ns are unweighted to show actual numbers of women in predictor categories. R^2 and R^2 change values for each equation and each hierarchical step are given at the bottom of each column, at the end of Table 4.

df = 1, p = .003) and 4.6 percent of 1981 NPDs age 50 or older ($\chi^2 = 7.54$, df = 1, p = .006).

- Remission of problem drinking was also most common among the youngest women; by 1986 only 27.4 percent of the 1981 PDs in the youngest age group still reported two or three problem drinking indicators, compared with 48.9 percent of 1981 PDs age 35 and older ($\chi^2 = 5.93$, df = 1, p = .015).
- Chronicity of problem drinking, on the other hand, was most likely among women age 35–49. Of the 1981 PDs in this age group, 57.2 percent continued to experience at least two problem drinking indicators in 1986, compared with 27.4 percent of women age 21–34 ($\chi^2 = 8.40$, df = 1, p = .004) and 35.6 percent of women age 50 or older ($\chi^2 = 1.84$, df = 1, p = .18; for 35 to 49-year-olds vs. all others, $\chi^2 = 7.97$, df = 1, p = .005).

Bivariate Relationships between Time 1 Predictors and Time 2 Drinking, and between Time 1 Drinking and Time 2 Conditions

Bivariate analyses consisted of a series of regression equations that used each Time 1 and interim predictor to predict the standardized residuals of each Time 2 drinking variable, and reciprocal analyses that used each Time 1 drinking variable to predict the standardized residuals of Time 2 or interim conditions corresponding to Time 1 predictors. These bivariate analyses showed many significant time-ordered relationships. Of 23 Time 1 variables, ten were significant predictors of Time 2 drinking variables among NPDs, and ten were significant predictors among PDs. Of ten interim variables, five were significant predictors of Time 2 drinking variables among NPDs, and six were significant predictors among PDs. In the other direction, of 19 Time 2 or interim conditions corresponding to Time 1 predictors, eight were significantly predicted by Time 1 drinking variables among NPDs, and 12 were significantly predicted by Time 1 drinking variables among PDs. Detailed results from the bivariate analyses are not presented here because of space limitations but are available upon request from the authors. Tables 2–4 include all Time 1and interim variables that significantly predicted any of the six Time 2 drinking variables among either PDs or NPDs in the bivariate analyses. Of the 33 potential

Note.—See Note, Table 2.

[a] In preliminary winnowing analyses, lifetime drug use was a stronger predictor of onset while current (1981) drug use was a stronger predictor of chronicity. Accordingly, only the lifetime use variable was included in the final regression equations for NPDs, and only the current use variable was used for PDs.

[b] Means and percentage rates are not provided for predictor categories with unweighted Ns less than 5.

predictors, only one—nontraditional feminine values—failed to predict any Time 2 drinking variables within either of the two subsamples.

Two variables often thought to be antecedents of problem drinking[16,17]—divorce or separation, and the "empty nest"—appeared to occur primarily after heavy or problem drinking in the present longitudinal bivariate analyses. The experience of a recent "empty nest" (last child leaving home in the past three years) did not predict Time 2 drinking behavior in either subsample, but among PDs, higher average consumption at Time 1 increased the likelihood that a respondent's last child would leave home during the three years prior to Time 2. Divorce and separation also occurred after rather than before heavy or problem drinking. Among NPDs, higher average consumption, heavy episodic drinking, and intoxication at Time 1 increased the likelihood of divorce or separation during the follow-up interval; similarly, among PDs, higher average consumption, intoxication, and PDI scores at Time 1 increased the chances of divorce or separation by Time 2. Contrary to expectations, being divorced or separated at Time 1 predicted lower levels of intoxication and lower PDI scores at Time 2 among PDs. We discuss additional bivariate relationships later in this paper, as an aid to interpreting multivariate findings.

Multivariate Prediction of Time 2 Drinking

Because some predictor variables were intercorrelated, it was important to examine the independent effects of each predictor, controlling for effects of all the others. Tables 2, 3, and 4 present the results of 12 unique hierarchical multiple regression equations predicting onset of problem drinking indicators among 1981 NPDs and chronicity of problem drinking indicators among 1981 PDs, using all predictors of a given Time 2 drinking variable surviving the winnowing process described above. Table 2 presents findings for Time 1 sociodemographic predictors; Table 3, findings for Time 1 personality and life-experience predictors; and Table 4, findings for all interim predictors. Although separated into three tables for convenience, the regression coefficients reflect the strength of each predictor when adjusted for *all* other predictors included in a given equation. Tables 2–4 also provide unweighted Ns, weighted means of

average daily consumption, and weighted percentage rates on each of the Time 2 drinking measures for each predictor's primary category of effect. These unadjusted means and percentages from simple bivariate time-lagged comparisons are presented for descriptive purposes. However, for brevity, we limit our discussion to the more rigorous and conservative multiple regression analyses.

The numerous relationships summarized in Tables 2–4 mean that some relationships will be statistically significant simply by chance. For this reason, our discussion focuses primarily on those variables that predicted more than one Time 2 drinking variable, and on variables that showed consistent relationships to drinking within both NPD and PD samples or for both Time 1 and interim measures.

Time 1 vs. Interim Variables: Tables 2–4 show that both longer term (Time 1) and more recent (interim) influences are important for the longitudinal prediction of women's drinking. However, the time-order of interim variables and drinking changes cannot be specified precisely with the data analyzed here. Interim variables are most likely to be antecedents rather than consequences of drinking if they 1) are also significant as Time 1 predictors, and/or 2) are not consequences of increased drinking or drinking problems in the two-way bivariate analyses reported earlier.

Predictors of Onset: As shown in Table 1, of 153 drinking women with no indicators of problem drinking in 1981, by 1986 17 (11 percent) had developed at least one indicator, and seven (4 percent) reported two or three indicators. Tables 2–4 show that the most consistent predictors of onset of heavier drinking or adverse drinking consequences were younger age, cohabiting at Time 1 or during the follow-up interval, lifetime use of drugs other than alcohol, and depressive episodes during the follow-up interval. Cohabiting was significant as both a Time 1 and an interim predictor and predicted the largest number of Time 2 drinking variables (average consumption, heavy episodic drinking, intoxication, and PDI). Younger age predicted increased intoxication, and in equations without interim variables also predicted increased heavy episodic drinking and PDI scores, while the number of drugs used up to 1981 predicted increased intoxication and PDI scores and, in an equation without interim variables, increased alcohol dependence symptoms. Two Time 1 predictors—nontraditional sexual behavior and low self-esteem—each increased the likelihood of heavy episodic drinking at Time 2.

Predictors of Chronicity: Of the 140 1981 PDs for whom complete data are available, 51 (36.5 percent) continued to report two or three problem drinking indicators in 1986, while 43 (31 percent) reported only one indicator and 46 (33 percent) no longer reported any indicators. As shown in Table 3, the most consistent predictor of persistent problem drinking was Time 1 sexual dysfunction, which predicted Time 2 intoxication, drinking problems, alcohol dependence symptoms, and PDI scores. Depressive episodes during the follow-up interval predicted continued intoxication and dependence symptoms, and in an equation without interim variables, Time 1 depression predicted continued drinking problems.

Five other variables predicted that PDs would drink more heavily at Time 2: interim unemployment and infertility, and Time 1 part-time employment, nontraditional gender traits, and frequent-drinking partner. PDs who had never married by Time 1 were more likely to report Time 2 drinking problems and (in equations excluding interim variables) to report more Time 2 intoxication and higher PDI scores. Use of drugs other than alcohol at Time 1 increased the likelihood of continued alcohol dependence symptoms and (in the equation excluding interim variables) heavier drinking.

Predictors of Remission: Although the analyses reported here were not designed to study remission of problem drinking, some variables that were expected to predict increased drinking had opposite effects in the longitudinal analyses (indicated by negative beta coefficients in Tables 2–4). For the most part, these were isolated effects, involving only single dependent variables. Consistent with the bivariate effects of Time 1 divorce, which reduced Time 2 intoxication and PDI scores among problem drinkers, becoming divorced or separated during the follow-up interval decreased the level of Time 2 alcohol dependence symptoms reported by problem drinkers.

Discussion

Patterns of Change

As in earlier reports based on retrospective[11] and longitudinal[14,18] data, women's drinking behavior in this study showed considerable change over a five-year period. Eleven percent of women with no signs of problem drinking in 1981 reported at least one problem drinking indicator in 1986, and 33 percent of the 1981 problem drinkers were completely free of problems five years later. This fluctuation may in part reflect the relatively mild definition of problem drinking used in this study, in contrast to more stable and interrelated alcohol problems associated with severe problem drinking or clinical alcohol dependence. However, our findings may also indicate that frequently drinking problems among women in the general, nonclinical population are sporadic or intermittent, possibly related to shifts in roles, contexts, and other circumstances in women's lives.

Age as a Mediator of Drinking Change

Women's problem drinking appears to change more in youth than later in life. Younger age significantly predicted the onset of intoxication among NPDs and significantly predicted reductions in average consumption among PDs. Women age 21–34 were more likely than older women to show both onset and remission of problem drinking indicators, while chronicity of problem drinking was greatest among women age 35–49.

These patterns are consistent with previous findings of higher rates of heavy episodic drinking, intoxication, and drinking problems among younger than among older women;[4] with data showing greater remission of drinking problems among younger than among older men;[19] and with findings of greater chronicity among middle-aged than among younger or older problem drinking women.[20] Younger women's greater movement both into and out of risky drinking behavior may relate to fluctuations in drinking contexts and drinking partners within this age group, as well as to transitions in employment, marital, and childbearing roles.[10,21]

Nontraditional Life-style and Onset

Nonproblem drinking women who reported nontraditional sexual behavior (premarital sexual relations and/or masturbation before age 21) at Time 1 and those who cohabited at Time 1 were more likely than other NPDs to report heavy episodic drinking at Time 2, and those beginning cohabitation during the follow-up interval were more likely to report other problem drinking indicators. Nontraditional sexual behavior and cohabitation may be indicators of a life-style associated with greater freedom from the traditional moral constraints that have restricted both sexual and drinking behavior, especially in women.[9,22] This greater freedom from conservative moral constraints may carry with it increased drinking opportunities and more permissive drinking norms that can heighten the risks of excessive drinking behavior. In addition, premarital and cohabiting relationships, lacking institutional protection or support, may involve stressful uncertainties that can lead to stress-medicating alcohol consumption.

Sexual Dysfunction and Chronicity

The best single predictor of chronicity was sexual dysfunction, which predicted continued intoxication, drinking problems, alcohol dependence symptoms, and PDI scores. This finding may reflect a tendency of problem drinking women to self-medicate sexual difficulties with alcohol, given prevailing cultural beliefs that drinking reduces sexual inhibitions and facilitates sexual pleasure.[9,23,24] Since heavy alcohol consumption has detrimental effects on physiological sexual functioning,[25] a self-reinforcing cycle may occur in which heavy drinking becomes both cause and consequence of sexual dysfunction. Our findings suggest a need to address issues of sexuality and sexual dysfunction in the treatment and recovery of alcoholic women, and a need to assess drinking behavior among women presenting with sexual dysfunction—needs also noted by recent clinical writers.[26–28] Because recent research on sexuality and drinking has focused mainly on women, it will be important to determine in future research the extent to which sexual experience and sexual dysfunction also influence drinking and problem drinking in men.

Role Deprivation and Women's Drinking

Other predictors of chronicity included never having been married, being employed part time at Time 1, and becoming unemployed during the follow-up interval. Part-time employment during the follow-up interval also predicted onset of drinking problems among 1981 NPDs, as did cohabiting. We have suggested elsewhere that a lack or loss of stable, full-time employment or marital roles (e.g., being unmarried, unemployed, or employed part time) may constitute "role deprivation."[10] Role deprivation may increase the risk of alcohol abuse by reducing women's self-esteem and feelings of social worth, and by reducing contact with role partners who could provide social support and feedback about excessive drinking behavior. Role deprivation as a risk factor for the onset and chronicity of problem drinking in women contrasts with earlier hypotheses regarding role conflict or role overload as causes of women's problem drinking[29][†] but is consistent with other evidence linking multiple roles to better health outcomes.[30,31]

Other Drug Use and Women's Drinking

In preliminary bivariate analyses, different Time 1 drug use variables predicted Time 2 drinking for NPDs as compared with PDs: the number of different types of drugs used *up to* 1981 predicted Time 2 alcohol dependence symptoms and PDI scores among NPDs, while the number of different types of drugs *currently* used in 1981 predicted Time 2 consumption, dependence symptoms, and PDI scores among PDs. Similarly, in the multivariate analyses reported in Table 3, drug use up to 1981 increased the likelihood of subsequent intoxication and higher PDI scores (as well as dependence symptoms in the equation omitting interim variables) among NPDs, while current drug use in 1981 predicted continued dependence symptoms (and, in the equation without interim variables, higher average consumption) at Time 2 among PDs.

These patterns suggest that the relationships between women's drinking and their use of other drugs may differ at different stages of problem drinking. The onset of problem drinking may be facilitated by a woman's long-term tendency to use various psychoactive drugs—perhaps in an alternating pattern over time—to feel better, to have a good time, or to cope with problems.[8] Once drinking problems have developed, the *concurrent* use of alcohol and other drugs may have synergistic effects—both physiological and behavioral—that increase the risks of continued or worsened alcohol abuse.

Unexpected Findings

From previous cross-sectional findings[10,29] and clinical-retrospective reports,[16,17] we expected that divorce or separation and children's departure from home would predict the onset and/or chronicity of women's problem drinking. However, in the longitudinal bivariate analyses both of these experiences were more likely to follow than to precede problem drinking, and in multivariate analyses, becoming divorced or separated during the follow-up interval reduced the risk of Time 2 alcohol dependence symptoms among PDs. Causes and effects may be more complex than the simple time sequences here can reveal. For example, it is possible that a troubled marriage (perhaps involving sexual dysfunction or a problem-drinking spouse) may lead a woman into problem drinking, which then remits when the marital distress is relieved by divorce or separation. A more refined and focused analysis is needed to distinguish the effects of two different types of role relationships: positive, gratifying role relationships, whose loss may lead to increased drinking, and negative, frustrating role relationships, whose termination may result in reduced distress and decreased drinking.

Different Predictors of Different Drinking Behaviors

In the results presented here, different Time 1 and interim variables predicted different Time 2 drinking variables. Furthermore, these links between predictor and drinking variables were sometimes different for PDs and NPDs. We are clearly not dealing with a unitary entity—"problem drinking"— but rather with multiple aspects of risky drinking behavior and drinking consequences, which may be influenced differently by different characteristics of the drinker and her social environment.

Despite this complexity, a few generalizations are possible. Predictors of drinking patterns (average consumption, heavy episodic drinking, and intoxication) are more often situational variables (e.g., cohabiting, unemployment, frequent-drinking partner) or life-style variables (e.g., nontraditional sexual behavior, nontraditional gender traits), whereas predictors of adverse drinking consequences (drinking problems, alcohol dependence symptoms) include more individual psychological variables (in particular, depression and sexual dysfunction). Psychological variables are also somewhat more prominent predictions of chronicity than of onset. These patterns suggest that the factors that lead a woman into high-risk drinking are not the same as the factors that sustain or exacerbate problem drinking. Participation in a nontraditional lifestyle, involving greater freedom from conventional moral constraints on women's drinking and sexual behavior, may entail both drinking opportunities and stressful uncertainties that can increase a woman's risk of hazardous drinking behavior. Whether problematic drinking behavior continues may depend on other factors, including the extent to which a woman uses alcohol to deal with personal or interpersonal difficulties such as sexual dysfunction, depression, or role deprivation. Delineating more fully the predictors of change at these different stages of problem drinking, for specific subgroups of women (e.g., by age), would allow primary and secondary prevention efforts to be targeted more precisely to the characteristics of the drinker, her social environment, and the extent to which she has progressed into problem drinking behavior. ☐

Acknowledgments

The research reported here was supported by Research Grant No. AA04610 from the National Institute on Alcohol Abuse and Alcoholism. We are grateful to staff of the National Opinion Research Center, which conducted the fieldwork for the 1981 and 1986 surveys; Martin R. Frankel of Baruch College, City University of New York, and NORC, who carried out the design effects analyses; Sue A. Russell, Perry W. Benson, and Brent W. Robertson for assistance with computer data analysis; and Lorraine J. Olson and Julie Isaacson Smith for secretarial support. An earlier version of this paper was presented at the Annual Meeting of the American Public Health Association, Chicago, Illinois, October 23, 1989.

APPENDIX— Personality, Sexuality, and Drinking Variables*

Personality

Depressive Episodes, up to 1981: Number of depressive episodes (two or more weeks of depressed mood and three or more depressive symptoms, occurring within the same month; from Diagnostic Interview Schedule[32]) up to 1981 (0, 1, $2^\dagger$).

Depressive Episodes, 1981–86: Presence of any depressive episodes (DIS criteria) in the five years before 1986 survey (yes/no).

Anxiety, 1981: Whether respondent considers self a nervous or anxious person at time of 1981 survey (yes/no).

Anxiety, 1986: Whether respondent considers self a nervous or anxious person at time of 1986 survey (yes/no).

Low Self-Esteem, 1981: With reference to 1981 self-description on seven gender-typed traits (Personal Attributes Questionnaire[33]), in how many ways respondent would like to be different (two levels: some or many ways vs. a few or none).

Low Self-Esteem, 1986: As measured in 1981 (four levels).

Nontraditional Gender Traits, 1981: Nine-level index based on two traditionally feminine traits—devotion to others, understanding of others (Personal Attributes Questionnaire[33])—dichotomized at most nontraditional quartile.

Nontraditional Gender Values, 1981: Eleven-level index based on two traditionally feminine values—marriage and parenthood[34]—dichotomized at most nontraditional quartile.

Nontraditional Gender Values, 1986: As measured in 1981.

Sexuality

Liberal Sexual Morality, 1981: Moral approval of adult premarital sex with love, in 1981 (four levels).[22]

Liberal Sexual Morality, 1986: As measured in 1981.

Nontraditional Sexual Behavior up to 1981: Index based on having had premarital sexual relations and/or a self-induced sexual climax before age 21, reported in 1981 (three levels). The index label "Nontraditional Sexual Behavior" refers to traditional sociocultural norms disapproving of both masturbation and premarital sex (particularly for women), and is not meant to imply that either behavior is presently nonconventional (i.e., exhibited only by a "deviant" minority of women). There is considerable evidence that traditional norms of this sort can continue to affect behavior and associated moral judgments even when behavioral violations and attitudinal exceptions achieve a modal, perhaps even a majority, level in a statistical sense.[35]

Sexual Dysfunction up to 1981: Index based on having experienced, up to 1981, lifetime lack of sexual interest, vaginismus, lifetime lack of orgasm, or unreliable (<50 percent of occasions) orgasm (four levels).[9] Questions based on Kaplan's classification of female sexual dysfunctions;[36,37] some questions adapted from Diagnostic Interview Schedule.[32] Male respondents answered parallel questions about male sexual dysfunctions.

Sexual Dysfunction, 1981–86: Index based on having experienced, between 1981 and 1986, lifetime lack of sexual interest, vaginismus, lifetime lack of orgasm, or unreliable (<50 percent of occasions) orgasm (four levels).

Drinking and Drinking Consequences

Average Consumption: Mean ounces of ethanol per day in last 30 days, estimated by calculating separately and summing for wine, beer, and liquor:

- (usual number of drinking days per month) × (usual number of drinks per typical drinking day) ×
- (size of drink: wine = 4 oz.; wine coolers = 5 oz. [1986]; beer = 12 oz. or 16 oz.; liquor = self-reported ounces per drink) ×
- (ethanol content: regular wine = 12 percent [1981], 11 percent [1986]; fortified wine = 18 percent; wine coolers = 12 percent [1986]; regular beer = 4 percent; malt liquor = 5 percent [1986]; low-calorie beer = 3 percent [1986]; low-alcohol beer = 2 percent [1986]; liquor = 41 percent [1981], 40 percent [1986])/30 days.

Heavy Episodic Drinking: Frequency, in past 12 months, of having six or more drinks of wine, beer, or liquor in a single day (three levels: never in past 12 months; one–three days or four–seven days in past 12 months; eight to 11 days in past 12 months to five or more days per week).

Intoxication: Frequency, in past 12 months, of drinking enough to feel drunk—where drinking "noticeably affected your thinking, talking, and behavior" (three levels: never in past 12 months; one–three days in past 12 months; four days in past 12 months to five or more days per week).

Problem Consequences: Number of drinking-related problems experienced in past 12 months, from a list of nine problems (see text, "Drinking Variables"; three levels: 0, 1, 2 or more).

Alcohol Dependence Symptoms: Number of alcohol dependence symptoms experienced in past 12 months, from a list of five symptoms (see text; three levels: 0, 1, 2 or more).

Problem Drinking Index (PDI): Index summing the occurrence in the past 12 months of 1) any intoxication, 2) any problem consequence, and 3) any alcohol dependence symptom (range: 0–3). Not to be confused with subsampling criteria for 1981 problem drinkers (at least two of the following: one or more ounces ethanol per day; one or more problem consequences in past 12 months; one or more alcohol dependence symptoms in past 12 months).

Race and Weight Change in US Women: The Roles of Socioeconomic and Marital Status

ABSTRACT

Background. The prevalence of overweight among Black women in the US is higher than among White women, but the causes are unknown.

Methods. We examined the weight change for 514 Black and 2,770 White women who entered the first Health and Nutrition Examination Survey (1971–75) at ages 25–44 years and were weighed again a decade later. We used multivariate analyses to estimate the weight-change effects associated with race, family income, education, and marital change.

Results. The mean weight change was greater for the Black women than the White women. Adjustments for height, duration of follow-up, baseline body mass index, and multiple demographic, social, and behavioral variables did not reduce this mean Black-White difference.

Conclusions. Among US women, Black race is independently associated with a reduced likelihood of major weight loss, but not with major weight gain. Women at greatest risk of weight gain are those with education below college level, those entering marriage, and those with very low family income. (*Am J Public Health* 1991;81:319–323)

Henry S. Kahn, MD, David F. Williamson, MS, PhD, and Judy A. Stevens, MS, MPH

Introduction

Cross-sectional surveys among United States adults have demonstrated that Black women have a higher prevalence of overweight than White women.[1,2] Overweight in US women is directly associated with low socioeconomic status.[3-6] Despite the association between Black race and low income or low education, controlling for socioeconomic status has not eliminated the overweight prevalence differences between Black women and White women.[1]

Prevalence alone does not explain the reasons for these observed associations. To understand the origin of overweight, we wondered whether race or socioeconomic factors during adulthood were independently associated with a woman's likelihood of gaining weight and whether marital status was involved (since this factor appears to be associated both with weight status[5] and with race).

Rac[illegible]cioeconomic status, or marital stat[illegible]ht contribute to overweight prevalence either by promoting weight gain or by inhibiting weight loss. To clarify the circumstances that led to the current weight distribution, we analyzed the mean weight changes, the major weight gains, and the major weight losses of a nationally representative prospective cohort of adult US women that was followed up over approximately a 10-year interval.

Methods

Study Population

This report analyzes public-use computer tapes containing the data from the First National Health and Nutrition Examination Survey[7,8] (NHANES-I) and the NHANES-I Epidemiologic Follow-up Study.[9] The subjects of NHANES-I, a probability sample of the US civilian, noninstitutionalized population resident in the contiguous 48 states, were initially interviewed and weighed in 1971–75. We limited our analysis to those who entered at ages 25–44 because these younger adult subjects had a greater risk of weight gain than older women.[10]

The initial NHANES-I population sample used for this analysis included 3,589 White women and 735 Black women between the ages of 25 and 44. (Seventy-two women in this age range with other racial designations are not included in this report.) Between 1982 and 1984 the NHANES-I Epidemiologic Follow-up Study successfully traced 3,210 (89 percent) of these White women and 621 (84 percent) of these Black women.[11] We excluded from this cohort women who had died since their initial examinations (50 Whites, 33 Blacks) and women for whom a valid, nonpregnant weight was not available at either baseline or follow-up (390 Whites, 74 Blacks). Thus, the 3,284 subjects included in this study of weight change represent 77 percent of the White women and 70 percent of the Black women initially enrolled in the NHANES-I cohort.

The mean duration of the follow-up interval was 10.1 ± 1.2 (SD) years.

This paper, submitted to the Journal February 5, 1990, was revised and accepted for publication October 23, 1990.

Definitions of Weight Change

Baseline measurements of height and weight were obtained under controlled conditions, with the subject wearing only disposable paper uniforms and foam rubber slippers. The follow-up weight was obtained in the subject's home after she removed her shoes and articles of heavy clothing. These follow-up values were corrected for the weight of the subject's indoor clothing by subtracting 1.6 kg from the measured weight.[10]

For each subject, weight change was categorized as either *major weight gain* (an increase of 13.0 kgs or more), *major weight loss* (a decrease of 7.0 kgs or more), or *mid-range weight change* (weight changes > −7 kgs but < +13 kgs).

Statistical Analysis

Considering weight change as a continuous variable, we used multiple linear regression models to estimate the effects associated with race, family income, education, and marital change. Our simple model adjusted each of these variables only for age, height, and duration of follow-up. Our fully adjusted model included adjustments for race, family income, education, marital change, age, height, duration of follow-up, body mass index (BMI, kg/m^2) at baseline, smoking, physical activity, parity, and rural/urban background (see Appendix for variable definitions).

Considering weight change as a categorical variable, we used multiple logistic regression analysis (employing the SAS procedure PROC LOGIST[12]) to estimate the odds ratio of either major weight gain or major weight loss for the various categories of race, family income, education, and marital change. Simple and fully adjusted models were developed as described above. For these analyses, the mid-range outcome of weight change was considered the "non-disease" group. Logistic regression analyses excluded 19 subjects with various unknown values.

We also performed multiple linear and logistic regression analyses stratified by overweight status at baseline. The overweight group at baseline (BMI ≥ 27.3) included 221 Blacks and 547 Whites; the group not overweight at baseline (BMI < 27.3) included 293 Blacks and 2,223 Whites.

Results

Mean Changes in Weight

The mean (±SD) change in weight was greater for Black women (3.8 ± 9.6 kgs) than for White women (2.8 ± 8.0) (difference = 1.0 kgs [95% confidence interval = 0.1, 1.9]). Blacks had a significantly wider variance of this weight-change variable (p = .0001, F-test for inequality of the variances). Adjustments for age, height, duration of follow-up, and other variables (Table 1) did not reduce this Black-White difference in mean weight change. Fully adjusted analyses stratified by overweight status at baseline showed that the Blacks' excess mean weight gain was 3.7 kgs (95% CI = 1.7, 5.8) among women who were initially overweight; among women not initially overweight, the Blacks' excess was only 0.8 kg (95% CI = −.1, 1.6).

The fully adjusted multiple linear regression model (Table 1, right column) demonstrated that women with only a 12th grade education had significantly greater weight gain compared to women who had gone beyond the 12th grade. When compared with women who were consistently married, women who became married during the 10-year interval experienced a greater weight gain, and women whose marriage ended experienced a relative weight loss.

Risk Factors for Major Weight Gain

Black women experienced a higher crude incidence of major weight gain (13.4 percent) than did the White women (7.7 percent).

Stayed unmarried	1.28	(0.92, 1.78)	1.00	(0.65, 1.52)

*Includes race, family income, education, marital change, age, height, duration of follow-up, BMI at baseline, smoking, physical activity, parity and rural/urban background.

When the logistic regression model was adjusted only for age, height, and duration of follow-up (Table 2, left column), Black race was significantly associated with major weight gain. Both low family income and low education were also associated with major weight gain (Table 2, left column).

However, in the fully adjusted model (Table 2, right column), Black race was only weakly associated with major weight gain. Stratification by overweight status at baseline did not alter this negative finding. In the fully adjusted model the strongest risk factors associated with major weight gain were very low family income (OR = 1.71) and becoming married during the follow-up interval (OR = 1.53).

The risk of major weight gain was also independently associated with being overweight at baseline in our fully adjusted model. Compared with women who entered the cohort in the lowest BMI stratum (BMI < 19.1), those in successively higher strata of baseline BMI had odds ratios for major weight gain of 0.64 (95% CI = 0.38, 1.07), 1.32 (0.79, 2.19), 2.23 (1.30, 3.82), and 2.26 (1.27, 4.04). If the larger multivariate model excluded adjustment for baseline BMI, the association between Black race and major weight gain yielded OR = 1.41 (95% CI = 1.00, 1.99).

Risk Factors for Major Weight Loss

Black women also experienced a higher crude incidence of major weight loss (8.8 percent) than did the White women (6.5 percent). However, the major weight loss logistic regression model, adjusting for age, height, and duration of follow-up (Table 3, left column), demonstrated that the odds ratio for Black race was only 1.35 (95% CI = 0.95, 1.92). After fully adjusting for other variables (Table 3, right column) Black race had an inverse (protective) association with major weight loss (OR = 0.64). Fully adjusted analyses stratified by baseline BMI indicated that this inverse association was limited to women who were overweight at baseline (OR = 0.53 [95% CI = 0.32, 0.89]) and was not observed among women who were not initially overweight (OR = 1.08 [95% CI = 0.51, 2.30]).

Very low family income was directly associated with the risk of major weight loss in the fully adjusted model (OR = 1.86).

Discussion

Several methodologic or interpretive issues should be considered when reviewing the weight-change experience of this large, representative, prospective cohort.

Approximately one-fourth of the population originally enrolled in NHANES-I was omitted from the analyses because of loss to follow-up or lack of a valid weight measurement. The effect of their missing data is unknown. However, any substantial bias would most likely have been due to diseases which might have caused these women both to be missing from the cohort and to have gained either more or less weight than those who participated fully. For these missing, hypothetically diseased, women to have changed substantially our results, they would have had to experience an extraordinary degree of consistently increasing weight (e.g. edema or ascites) or consistently decreasing weight (e.g. cachexia). This is unlikely since the enrolled cohort was relatively young and during the 10-year interval only a small proportion would have been expected to acquire a major, chronic disease. Systematic biases due to other causes seem even less likely.

Our principal outcome events, major weight gains and losses, were determined by the difference between weight measurements made at only two points widely separated in time. Fluctuations in weight that may have occurred during the decade of follow-up are not reflected in our data. Hence our case definitions for both major weight gain and major weight loss probably failed to include everyone who had a major weight change between baseline and follow-up exams. Semi-annual weights obtained in a four-year Dutch study suggest that overweight women and women with the highest rates of weight gain or weight loss are also the women who experience the widest weight fluctu-

TABLE 3—Effect of Race, Family Income, Educational Attainment, and Marital Change on the Risk of Major Weight Loss (MWL), by Multiple Logistic Regression; US Women Aged 25–44 at Baseline Who Experienced MWL (n = 225) or Mid-range Weight Change (n = 2,759) between NHANES-I Baseline (1971–75) and NHANES-I Follow-up (1982–84)

ations.[13] Thus, our observed incidence rates for major weight change likely represent low estimates for the occurrence of major weight gain or major weight loss over a 10-year period.

After adjusting for multiple variables, Black women had a greater increase in mean weight compared to White women in this cohort (Table 1). This finding is consistent with US prevalence data. However, after full multivariate adjustments we found that Black women were not significantly more likely than White women to experience a major weight gain (Table 2). The racial effect on mean weight change could readily be viewed as a result of the Black women's decreased tendency to lose weight (Table 3). Our analyses stratified by baseline overweight status demonstrated that it was only among women who were overweight at baseline that the Blacks showed a clear excess of mean weight gain and a protective effect against major weight loss.

This reduced likelihood of weight loss among overweight Black women deserves further study. It could reflect acquired cultural factors (e.g. specific dietary exposures, perceptions of ideal body size) that may have made Black women less able or less motivated than White women to lose weight. Genetic factors may also play a role. Our data provide no basis for choosing among these explanations. As with any studies that collect data on race,[14] the NHANES-I criterion for being Black (or White) may have historical, social, or cultural significance that exceeds any clear genetic meaning.

We noted that the risks of both major weight gain and major weight loss in the NHANES-I follow-up cohort were directly associated with high BMI at baseline. Similar observations have been made previously in other female populations from the US[15] and Europe.[13,16] Since the Black women in our study were more overweight at baseline than were the White women, preexisting weight status was a potential confounder of the relationship between women's weight change and race. If the baseline BMI was not taken into account, multiple adjustments for current social, demographic, and behavioral factors reduced the Blacks' odds ratio for major weight gain from 1.79 to 1.41. Including adjustment for baseline BMI (along with the other variables) further reduced the major weight gain odds ratio to 1.21. It is possible that our adjustment for baseline BMI served as a surrogate adjustment for the prior weight-related experiences of cohort members before they entered the follow-up study. If low income and low education are associated with increased mean or major weight gains, then these circumstances common among US Black women before they entered NHANES-I may have explained their having baseline BMIs that were higher than those of the White women.

The serious health risks associated with adult overweight and the low success rates associated with its treatment suggest that we must develop a public health strategy for the prevention of weight gain among adults. Our findings indicate that women in greatest need of help in preventing weight gain are those with education below college level, those with low family incomes, and those who become married. Black race does not appear to be an independent adult risk factor for weight gain. Future research should address the mechanisms by which the diet and social stresses of women with low socioeconomic status may influence their weight changes. Studies of eating practices and physical activity changes associated with entering marriage might likewise contribute to the prevention of adult weight gain. ☐

APPENDIX

Definitions of Other Variables

Race was classified by interviewer observation as "White, Negro or other"; if the appropriate category could not be marked by observation, then the respondent was asked her race. (Hispanics not regarded as "Negro" were included with "White" unless definitely known to be American Indian or other non-White race, in which case they were excluded from this analysis.)

The baseline interview also categorized the subject's *educational level* as the "highest grade of regular school ever attended."

The *family income* variable used categorical interview information collected both at NHANES-I baseline and at follow-up to classify women as having very low, moderately low, or adequate levels of family income across the ten-year interval:

	Family Income at Follow-up (1982–84)		
	< $15,000	15,000–$19,999	$20,000+
Family Income at Baseline *(1971–75)*			
$10,000 +	Adequate	Adequate	Adequate
$7,000–$9,999	Mod. Low	Mod. Low	Adequate
< $7,000	Very Low	Mod. Low	Adequate

Based on contemporaneous median family incomes in the U.S.,[17] women in the "very low" income level had family incomes below about 59% of median family incomes for both time periods. Women in the "moderately low" income level had family incomes below about 82 percent of median family incomes (but not repeatedly below about 59 percent of median) for both time periods.

Marital change was defined as consistently married, marriage ended, became married, or stayed unmarried, depending on whether the subject reported being married or not at baseline and at follow-up. Women who might have become divorced and remarried during the follow-up interval were included within the "consistently married" category.

Age at baseline was stratified by five-year intervals.

Height and *duration of follow-up* were treated as continuous variables.

The subjects' *weight status at baseline,* as estimated by body mass index (BMI, kg/m^2), was divided into five categories with break points at BMIs of 19.1, 23.0, 27.3, and 32.3.

Among the additional variables considered as possible confounders, *smoking status* was defined at follow-up as never smoked, continuing smoker, and ex-smoker. Self-described recreational and nonrecreational *physical activity,* determined at both baseline and follow-up, was defined in three levels as consistently low, moderate or inconsistent, and consistently high. *Parity* at the time of follow-up was stratified as 0, 1-2, 3-4, and 5+. *Rural/urban background* was determined by the subject's response at follow-up to the question "Would you say that you have lived most of your life in a rural area, or the city or in the city suburbs?"

Gender Differences in Cigarette Smoking and Quitting in a Cohort of Young Adults

Phyllis L. Pirie, PhD, David M. Murray, PhD, and Russell V. Luepker, MD

ABSTRACT

Background. Smoking among young women is associated with a variety of negative health outcomes. Gender specific influences on smoking, quitting and attempting to quit are hypothesized to occur and may have implications for cessation programs.

Methods. Telephone surveys were conducted in a large (n = 6,711) cohort of young men and women (average age 19.2 years) which was first established in 1979 and has been resurveyed several times since then. Questions concerned smoking, successful and unsuccessful attempts to quit, withdrawal symptoms during quit attempts, and concerns about quitting.

Results. More women than men reported current smoking (26.5 vs 22.6 percent), but quitting attempts, successful and unsuccessful, were equally common. Withdrawal symptoms were reported equally, except for wanting to eat more than usual and weight gain, both of which were reported more often by women than men. Women smokers reported substantially more concern about weight gain if they quit smoking (57.9 vs 26.3 percent expressing concern).

Conclusions. Targeted programs are needed to address issues of concern to young women smokers, particularly fear of gaining weight. (*Am J Public Health* 1991;81:324–327)

Introduction

The prevalence of smoking and the burden of smoking-related illness in this country are beginning to shift toward women. Among men, cross-sectional surveys on smoking status have presented a picture of steadily declining smoking rates from the 1960s to the present, coupled with a steady increase in the number of ex-smokers.[1-3] Among women, the percentage decline in smoking prevalence has been smaller.[3,4] Smoking prevalence rates in the youngest groups of adult women are beginning to exceed those in men, at least among whites,[1,5,6] and overall smoking rates among women are projected to exceed those among men by the latter part of the 1990s.[7]

Smoking in young women is particularly troubling because it not only poses hazards to their own long-term health,[8] but has immediate impacts on reproductive function[9,10] and the health of their children.[11,12] With a large population of young women continuing to take up smoking, there is a clear need to learn more about ways to help them quit smoking, as well as barriers to their quitting. This paper is an exploration of smoking, quitting, and attempted quitting behavior in a population of young adults, with particular attention to the experiences of young women.

Methods

The young adults in our study originally comprised the entire seventh-grade enrollment of four suburban districts in the Minneapolis-St. Paul, Minnesota, metropolitan area in two subsequent years, 1979 and 1980. They took part in two adolescent smoking studies, which have been described elsewhere.[13-15] Briefly, as seventh-graders, these students were exposed to variations of a "social influences" smoking prevention curriculum; long-term follow-up demonstrated modest differences in smoking prevalence among students in the various conditions through about eleventh grade,[14] but no differences after that time.[15]

The cohort of participating students was reconstructed in 1984-85 and resurveyed annually through 1988.[16,17] The data reported here are from the 1986-87 follow-up survey, at which time the participants were one or two years out of high school. The response rate for this survey was 94.6 percent, representing 6,711 of a total possible 7,096 interviews. An additional 28 members of the initial cohort were deceased or severely disabled and thus unavailable for interview.

Participants were randomly assigned to one of 11 months (excluding December) for annual follow-up and interviewed by telephone between October 1986 and November 1987. Data collected during the interview included items on current and former smoking status, quit attempts, withdrawal symptoms, perceived barriers to quitting, perceived pressures to quit, current weight and concern about weight. The smoking status variables reported here were based on self-report. In a separate analysis, a sample of individuals provided saliva samples for validation of smoking status;[18] results indicated that telephone self-report data are largely accurate in this population, although recent

TABLE 1—Smoking and Quitting Behaviors in a Cohort of Young Men and Women with an Average Age of 19.2 Years

Behaviors	Men (95% CI) n = 3455	Women (95% CI) n = 3256
Of total		
% Ever smoked ≥ 100 cigarettes in lifetime	32.1 (30.5, 33.7)	37.6 (35.9, 39.3)
% Current smokers	22.6 (21.2, 24.0)	26.5 (25.0, 28.0)
% Ex-smokers	9.6 (8.6, 10.6)	11.2 (10.0, 12.2)
Of Current Smokers	(n = 779)	(n = 863)
Number of cigarettes smoked in the last 24 hours	16.2 (13.6, 18.8)	14.3 (12.0, 16.6)
% Tried to quit in past 12 months	62.6 (59.2, 66.0)	66.9 (63.8, 70.0)
% Would like to quit	76.1 (73.1, 79.1)	72.4 (69.4, 75.4)
% Changed brands in past 12 months to reduce tar and nicotine	32.4 (29.1, 35.7)	34.5 (31.3, 37.7)
Of those who have tried to quit in the last 12 months	(n = 487)	(n = 575)
Number of quit attempts lasting more than 1 week	1.6 (0.5, 2.7)	1.6 (0.6, 2.6)
Length of longest quit attempt (days)	28.5 (24.5, 32.5)	36.7 (32.8, 40.6)

TABLE 2—Self-Reported Smoking Habits Reflective of Addictive or Dependent Smoking Among Young Adult Current Smokers, by Gender

Smoking Habits	Men (95% CI) n = 779	Women (95% CI) n = 863
% Always inhale	93.6 (91.9, 95.3)	93.4 (91.7, 95.1)
% Smoke more in morning than in rest of day	13.4 (11.0, 15.8)	13.3 (11.0, 15.6)
% Smoke within 30 minutes of getting up	44.2 (40.7, 47.7)	35.6 (32.4, 38.8)
% First cigarette in morning is one would most hate to give up	32.3 (29.0, 35.6)	24.9 (22.0, 27.8)
% Find it hard not to smoke in places where it's forbidden	13.6 (11.2, 16.0)	11.6 (9.5, 13.7)
% Smoke even when ill	16.5 (13.9, 19.1)	12.6 (10.4, 14.8)

quitting may be overreported, a discrepancy unlikely to affect the gender-specific comparisons reported here.

Simple proportions and their 95 percent confidence intervals are reported for categorical variables, and means and their confidence intervals for continuous variables. All analyses were conducted using SAS.[19]

Results

The average age of the respondents in this survey was 19.2 years; 51 percent were male. Nearly all of the students were White; 37 percent were enrolled in four-year colleges and 23 percent in vocational schools or two-year colleges. All but 7 percent had graduated from high school.

As shown in Table 1, more women than men were current smokers, and more had ever smoked. The proportion who reported themselves as former smokers, however, was approximately the same in men and women. No gender differences were seen in amount of current smoking or on most of the questions designed to elicit quitting behaviors, although women self-reported slightly longer quit attempts.

The genders differed slightly on items reflecting addictive or dependent smoking[20] (Table 2) with more men reporting that they smoked within 30 minutes of getting up and that the first cigarette in the morning was the one they would most hate to give up.

Both current and former smokers were asked about withdrawal symptoms (Table 3), with unsuccessful quitters reporting higher withdrawal symptoms on all symptoms except weight gain. Women were more likely than men to report wanting to eat more than usual, and they also reported more weight gain. The suggestion that weight gain is differentially a problem for women (as compared to men) is not supported by the self-reported weights, however. Among women, the quitters weighed about the same as current smokers (127.2 lbs for each group, on average), while among men, the successful quitters were heavier than current smokers (167.3 vs 162.0 lbs).

Finally, we examined various beliefs about the social and physical aspects of quitting smoking which may act as barriers to quitting, as well as potential social pressures to quit (Table 4). Women were more likely to agree with two of the "barriers" items: "If I quit smoking, I would probably gain a lot of weight" and, "If I quit smoking, it would be hard to go out with friends who smoke." Women were also more likely to agree that they felt social pressure to quit, reporting that, "A doctor has strongly urged me to quit smoking" and, "The people I'm closest to would like me to quit smoking."

Discussion

Contrary to reports in the past that women smokers have had a much harder time quitting smoking than men,[20,21] these data indicate that both quitting attempts and successful quitting are equally common in both genders for young adults. This may be a positive indication that future smoking patterns will show similar trends for men and women, with higher quit rates among women than are seen in existing cross-sectional surveys of adult women. On the other hand, these data do indicate that more young women than young men are beginning to smoke and are continuing the habit into early adulthood, a time when the risks of smoking to their personal and reproductive health begin to be manifest.

It is interesting that the unsuccessful quitters reported higher levels of withdrawal symptoms on nearly all items, suggesting that elevated levels of withdrawal symptoms may have prevented their successful cessation, although the unsuccessful nature of the attempt may also have led them to overreport symptom severity in order to rationalize failure.

At least one study has found that women who attempt to quit smoking report more severe withdrawal symptoms than do men,[22] although others have failed to confirm this finding.[23,24] In the young adult cohort reported here, among both successful and unsuccessful quitters, women did not generally report more withdrawal symptoms than did men, in

TABLE 3—Percent of Young Adults Reporting Withdrawal Symptoms, by Gender:

Withdrawal Symptoms	Men (95% CI) n = 454	Women (95% CI) n = 538
*Current smokers—%**		
Irritability or impatience	54.8 (50.2, 59.4)	56.7 (52.5, 60.9)
Difficulty concentrating	28.2 (24.1, 32.3)	26.4 (22.7, 30.1)
Restlessness	57.7 (53.2, 62.2)	53.9 (49.7, 58.1)
Craving for a cigarette	82.8 (79.3, 86.3)	81.9 (78.6, 85.2)
Wanted to eat more than usual	31.9 (27.6, 36.2)	49.5 (45.3, 53.7)
Fatigue or lack of energy	19.0 (15.4, 22.6)	19.6 (16.2, 23.0)
Wanted to drink more fluids than usual	48.0 (43.4, 52.6)	41.5 (37.3, 45.7)
Weight gain	14.5 (11.3, 17.7)	26.1 (22.4, 29.8)
Former smokers—%†	(n = 229)	(n = 224)
Irritability or impatience	40.6 (34.2, 47.0)	33.0 (26.9, 39.2)
Difficulty concentrating	15.7 (11.0, 20.4)	8.9 (5.2, 12.7)
Restlessness	36.7 (30.4, 42.9)	29.9 (23.9, 35.9)
Craving for a cigarette	64.6 (58.4, 70.8)	62.5 (56.2, 68.8)
Wanted to eat more than usual	26.2 (20.5, 31.9)	47.8 (41.2, 54.3)
Fatigue or lack of energy	13.5 (9.1, 18.0)	15.2 (10.5, 19.9)
Wanted to drink more fluids than usual	35.4 (29.2, 41.6)	28.6 (22.6, 34.5)
Weight gain	19.2 (14.1, 24.3)	29.5 (23.5, 35.4)

**Current smokers who have attempted to quit within last 12 months; for most recent attempt lasting more than 24 hours.

†Former smokers, who quit within one year of interview.

TABLE 4—Percent Agreement with Statements Reflecting Barriers and Pressures to Quit Smoking Reported by Young Adult Current Smokers, by Gender

Barriers/Pressures	Men (95% CI) n = 779	Women (95% CI) n = 863
Barriers to Quitting—%		
If I quit smoking, I would probably gain a lot of weight	26.3 (23.2, 29.4)*	57.9 (54.6, 61.2)
If I quit smoking, I would feel tense and irritable	62.1 (58.7, 65.5)	67.7 (64.6, 70.8)
I enjoy smoking too much to quit	50.4 (46.9, 53.9)	50.9 (45.6, 54.2)
If I quit smoking, it would be hard to go out with friends who smoke	32.7 (29.4, 36.0)	46.5 (43.2, 49.8)
If I got tense and irritable from not smoking, it would make the people I'm closest to unhappy	54.7 (51.2, 58.2)	59.2 (55.9, 62.5)
Pressures to Quit—%		
A doctor has strongly urged me to quit smoking	20.2 (17.4, 23.0)	31.5 (28.4, 34.6)
The people I'm closest to would like me to quit smoking	63.5 (60.1, 66.9)	70.6 (67.6, 73.6)

*95% confidence interval.

fact, among the successful quitters, men tended to report more symptoms. Weight concerns, however, emerged in opposition to this general pattern, with both successful and unsuccessful quitters among women reporting eating more and gaining weight during quit attempts. Current women smokers strongly endorsed the notion that they would gain weight if they quit smoking. Interestingly, although women reported more concern about weight, the evidence did not suggest any large weight gains among the successful quitters in this group, who weighed, on average, exactly as much as their smoking counterparts. Although several published studies indicated that weight gain after quitting smoking was greater in women than men,[1] that finding was not supported in this population. It was clear, however, that concern about gaining weight is much more common in women than in men, and that such concern was excessive in light of the magnitude of the problem. While 57.9 percent of women smokers in our population agreed that they would probably gain a lot of weight if they quit smoking, only 26.2 percent of quit attempters and 29.5 percent of actual quitters reported gaining weight. Even those gains must have been modest or readily controlled, as average weights for quitters were not higher than for current smokers.

One limitation of this study is the nonrepresentative nature of the sample, which consists primarily of White young adults, the majority of whom are pursuing education beyond high school. This is reflected in the self-reported smoking rates, which are lower than those reported from national samples.[4]

The data reported here provide support for the observation that young women are smoking cigarettes in greater numbers than young men, and concern about weight gain emerges as a major issue for these young women smokers. Given the risks to their familes as well as to themselves, public health cessation efforts targeted to women continue to be warranted. Targeted programs need to address issues of concern to women, particularly fear of gaining weight. ☐

Nominations Invited for APHA 1991 Food & Nutrition Awards

The Food and Nutrition Section, American Public Health Association, is announcing the availability of the Helen R. Stacey and Joseph A. Walsh Awards for Graduate Education at the Master's Degree level in Public Health Nutrition. Three awards are given consisting of $2,000 each. These awards must be used for the academic year 1991–92. *Applications must be submitted no later than May 1, 1991.*

Nominations are being solicited for the Mary C. Egan Award for Outstanding Professional Contributions and Service in Public Health Nutrition. This award carries with it a $1,000 honorarium. *Nominations must be submitted no later than May 1, 1991.*

Applications and nomination forms may be secured from:
Elvira E. Jarka, MS, RD, Chairperson
Awards Committee, F&NS, APHA
Lake County Health Department
2303 Dodge
Waukegan, IL 60085

Intake of Tapwater and Total Water by Pregnant and Lactating Women

Abby G. Ershow, ScD, Linda M. Brown, MPH, and Kenneth P. Cantor, PhD

ABSTRACT

Background. Despite theoretically higher requirements for water due to physiologic demands of pregnancy and lactation, little is known of actual ranges of intake in pregnant and lactating women.

Methods. Population-based estimates of total water and tapwater intake in women of reproductive age were derived using data from the 1977–78 USDA Nationwide Food Consumption Survey. Three-day average intakes were calculated for 188 pregnant women, 77 lactating women, and 6,201 non-pregnant, non-lactating control women.

Results. Total water intake (mean ± SD) was 1,940 ± 686 g/day (median 1,835) for control women, 2,076 ± 743 g/day (median 1,928) for pregnant women and 2,242 ± 658 g/day (median 2,164) for lactating women. Tapwater intake was 1,157 ± 635 g/day (median 1,065) for control women, 1,189 ± 699 g/day (median 1,063) for pregnant women, and 1,310 ± 591 g/day (median 1,330) for lactating women. Total water intake was equal to or greater than 3,000 g/day among 7 percent of control women, 11 percent of pregnant women, and 13 percent of lactating women. Tapwater intake was equal to or greater than 2,000 g/day among 10 percent of control women, 15 percent of pregnant women, and 8 percent of lactating women.

Conclusions. These results should be useful in estimating amounts of nutrients and toxic substances that women of reproductive age obtain through the water supply. (*Am J Public Health* 1991;81:328–334)

Introduction

Although weight gain during pregnancy and milk output during lactation cause a theoretical increase in the physiological requirement for water,[1] the actual range of water intake among pregnant and lactating women is not known.[2] The relative importance of water as a dietary source of nutrients such as calcium cannot be evaluated in the absence of intake data. Furthermore, secondary exposure of a fetus or nursing child to toxic substances in the water supply makes accurate data on quantities of water consumed by the mother particularly important in establishing criteria for setting allowances of contaminant levels. To make population-based estimates of quantities and sources of tapwater and total water ingested by pregnant and lactating women, we used data from a large national US Department of Agriculture (USDA) dietary survey,[3–5] which provided an opportunity to consider water intake from all sources including solid foods. For purposes of comparison, we have also estimated intakes for similarly aged non-pregnant, non-lactating women who participated in the same survey.

Methods

Survey Design

In 1977–78 the USDA conducted the Nationwide Food Consumption Survey (NFCS) to gather dietary information on individuals living in randomly sampled nonmilitary households in the contiguous 48 states.[3] The NFCS first sampled households and asked the head of household to complete a seven-day household food use and purchase record. Of the 20,812 households contacted, 14,930 (72 percent) agreed to participate in this activity. Ninety-four percent of the individuals sampled from the participating households completed an interview that included a 24-hour recall; they were then asked to keep a food diary for the next two days.[6]

Participating in the Individual Intake Survey were 30,770 persons.[3] Of these, 87 women stated that they were nursing a child aged two years or less, and 214 women stated that they were four or more months pregnant (women less than four months pregnant were classified by the USDA as not pregnant).[3,4] The pregnant and lactating women interviewed for the NFCS were 15–49 years of age; thus, for potential control subjects, we identified all female NFCS participants 15–49 years old who were neither pregnant nor lactating (n = 7,227).

Analytic Sample

Our data analysis was confined to those NFCS participants having complete and usable data on demographic variables of interest, self-reported weight and height, and all foods, beverages, and drinking water consumed for three consecutive days. Overall, 86 percent of interviewed participants,[7] including 188 pregnant women, 77 lactating women, and 6,201 non-pregnant, non-lactating control women, fit these criteria.

Address reprint requests to Abby G. Ershow, ScD, Nutritionist, Lipid Metabolism-Atherogenesis Branch, National Heart, Lung and Blood Institute, Bethesda, MD 20892. Ms. Brown is an Epidemiologist with the Biostatistics Branch, National Cancer Institute; Dr. Cantor is an Epidemiologist, Environmental Epidemiology Branch, NCI. This paper, submitted to the Journal June 23, 1989, was revised and accepted for publication August 6, 1990.

To compensate for deletions, we developed a weighting factor ("NCI weighting factor") equal to the inverse of the retained (i.e., not deleted) proportion of participants in each age-sex-race-region-season stratum.[7] This NCI weighting factor was derived for the entire data set and applies to the pregnant and lactating participants as well; it did not reflect any assumptions regarding diet or water intake of non-respondents. The retained participants did not differ from the original sample with regard to the distribution of values for age, sex, race, region, season of interview, urbanization, and education of heads of household,[7] and for this reason we consider our analytic sample to be satisfactorily representative of all surveyed participants. All calculations incorporated the NCI weighting factor as well as a USDA weighting factor that reflected the interview completion rate in each sampling stratum.[3,4,7]

Definition of Terms

"Drinking water" refers to plain water consumed directly as a beverage, but does not include tapwater used to prepare foods and other beverages. "Tapwater" includes drinking water as well as tapwater added in final preparation of foods and tapwater-based beverages. "Total water" includes all water from tapwater and non-tapwater sources, including water contained in food.

Calculation of Tapwater and Total Water Intake

The methods, coding procedures, and specific assumptions used in calculating tapwater and total water intake from the 4,545 foods and beverages reported as consumed by NFCS study participants have been fully described elsewhere[7] and will be summarized here. For all food items listed on the surveyed individuals' dietary records,[5,8] an experienced nutritionist (author AGE) estimated the proportion of the total water content likely to derive from household tapwater added during preparation. Examples of this estimated tapwater proportion are: 100 percent (tea, coffee); 84 percent (reconstituted frozen fruit juices); 50 percent (most reconstituted canned soups); 0 percent (meats, fresh whole milk, fresh fruit, carbonated beverages). These tapwater proportion values were merged with data on the water content of foods[5,7] and on the quantities of foods (including soups) and beverages consumed,[4] providing an estimate of total water and tapwater intake from all foods and beverages. To these estimates we added the cups of drinking water consumed each day, yielding the quantities of total water and tapwater from each dietary source for each individual over three days.[7] The original USDA dietary data were recorded in common household units and converted to grams during data processing.[8] Our results are expressed in grams, in keeping with the format of the public use data tapes.[4]

Statistical Methods

All calculations and statistical procedures were conducted using the SAS software package,[9] and incorporated weighting factors (see above) reflecting the interview completion rate in each sample stratum and the deletion of participants with incomplete data.[7] Values represent three-day averages for each individual. All values reported in the text represent mean ± standard deviation. Values for the fraction of total water intake provided by tapwater (see Table 3, below) represent the mean proportion for individuals.[10] Values for the fraction of total water and tapwater intake provided by various dietary sources (see "Results," below) represent the population proportion.[10]

For the entire group of study subjects (n = 6,466), sources of between-individuals variation in daily total water and tapwater intake were examined using analysis of variance (ANOVA) for unbalanced designs (PROC GLM).[9] The model included main-effects terms for reproductive status, race, urban/rural residence, region, and season; and covariate terms for age, weight, height, and mean household educational level. Education of the heads of household was a surrogate measure for income, which many participants (21 percent) would not report. Comparisons of means were made using a multiple comparison test (LSMEANS PDIFF) based on the analysis-of-variance model, in which the significance of each contrast was determined after adjusting for all other main effects and covariates.[9]

Results

Characteristics of Participants

Demographic and physical characteristics of the study participants are shown in Table 1. The women were fairly evenly distributed among the northeastern, southern, midwestern and western regions of the country. Interviews took place during all four seasons of the year. Most of the women were white and lived in urban or suburban rather than rural areas. The lactating women were generally older than the pregnant women and tended to live in households with a higher level of education. Self-reported heights and weights of our study sample compared favorably with physical measurements of height and weight made on adult females participating in the second US National Health and Nutrition Examination Survey (NHANES II).[11]

Total Water Intake

Effect of Reproductive Status. Total water intake of study participants is shown in Table 2. Mean and median daily consumption of total water for all participants was approximately 2 liters (i.e., 2,000 g). The upper ranges of intake, however, were much higher. Seven percent of control women, 11 percent of pregnant women, and 13 percent of lactating women consumed 3 liters (3,000 g) or more total water per day. Three percent, 4 percent, and 3 percent of control, pregnant, and lactating women, respectively, had total daily water intakes equal to or exceeding 3.5 liters (3,500 g).

Reproductive status was significantly associated with total water intake ($p < .001$). Lactating women consumed the largest quantity (g/day) of total water ($p < .001$ compared with control mean), but the mean intake of pregnant women was also significantly elevated ($p < .05$ compared with control women). The total water intake of lactating women was considerably higher than that of pregnant women, but this difference was not statistically significant due to relatively small numbers of participants.

Lactating women also had the highest mean intake of total water when expressed in terms of body weight ($p < .01$ compared with both control and pregnant women). Total water intake per unit of body weight did not differ between pregnant and control women.

Of the 77 lactating women, 64 had infants who also were NFCS study subjects; no information was available regarding the other 13 infants. Total water intake of these 64 lactating mothers was not significantly correlated with either the age (mean = 5 mo) or weight (mean = 7 kg) of their infants.

Total water intake per unit of energy (i.e., g/kcal/day) did not vary as a function of reproductive status. This reflects the parallel increase of water and energy intake: control, pregnant, and lactating women consumed 1,592 ± 561, 1,719 ± 556, and 1,887 ± 626 kcal/day, respectively (mean ± SD).

Effects of other factors. The effects of factors other than reproductive status on total water intake were also examined in the entire sample of 6,466 women. The most striking effects were due to regional variations in residence. Total water intakes were lowest in the northeast (mean ± SD 1,827 ± 819 g/day; n = 1,551), intermediate in the south (1,955 ± 844 g/day; n = 2,147) and midwest (1,972 ± 912 g/day; n = 1,666), and highest in the west (2,063 ± 1,096 g/day; n = 1,102). Regarding another aspect of residence, rural women consumed more total water than urban/suburban women (1,997 ± 866 g/day, n = 1,885 vs 1,931 ± 925 g/day, n = 4,581).

Effects of race on total water intake may have been due to variation in food and beverage preferences. The small number of non-White, non-Black women had higher total water intakes (2,017 ± 957 g/day, n = 241) than White women (1,953 ± 898 g/day, n = 5,379), who in turn had higher total water intakes than Black women (1,893 ± 960 g/day, n = 846). Seasonal variation in total water intake was due primarily to elevated intake during the summer (2,011 ± 1,006 g/day; n = 1,384). Intakes were very similar in the autumn (1,916 ± 930 g/day; n = 1,617), winter (1,938 ± 960 g/day; n = 1,523), and spring (1,926 ± 762 g/day; n = 1,942).

Tapwater Intake

Effect of reproductive status. Mean and median daily consumption of tapwater for all groups (Table 3) was approximately 1.1 liters (1,100 g). Two liters (2,000 g) or more of tapwater were consumed daily by 10 percent, 15 percent, and 8 percent of control, pregnant, and lactating women respectively. Four percent of control and pregnant women and 3 percent of lactating women ingested 2.5 liters (2,500 g) or more of tapwater daily. Similar to the situation for total water, lactating women had the highest mean daily tapwater consumption ($p < .01$ compared with control women). The difference in tapwater intake between lactating women and pregnant women was nearly as large, but not significant due to small numbers. Pregnant women consumed only slightly more tapwater than control women. When compared with control women, mean tapwater intake per unit of body weight (i.e., g/kg/day) was also significantly higher in lactating women ($p < .05$) but not in pregnant women. Pregnant women actually had a slightly lower intake of tapwater per kg body weight than control women, possibly reflecting weight gain in pregnancy or a shift to sources of fluid (such as milk) that contain relatively little tapwater.

Effects of other factors. Effects on tapwater intake of factors other than reproductive status were similar in direction to those for total water, but the magnitude of the effects was smaller. Region again was the strongest residential factor. Intake was highest in the south (1,228 ± 798) and west (1,208 ± 982) and intermediate in the midwest (1,166 ± 857), whereas women in the northeast consumed less tapwater (1,034 ± 743 g/day) than in all other regions. Rural women consumed more tapwater (1,237 ± 819 g/day) than urban/suburban women (1,132 ± 847 g/day). Tapwater intake of non-White, non-Black women (1,232 ± 815 g/day) was higher than that of either White women (1,159 ± 841) or Black women (1,143 ± 849 g/day). Seasonal intake, which varied only slightly, was highest in the summer (1,198 ± 918), followed by winter (1,165 ± 895), autumn (1,144 ± 861), and spring (1,130 ± 711).

Sources of Total Water and Tapwater

The contribution of various dietary sources to total water intake is shown in Table 4. The reader should note that the mass of the non-water fraction of the foods does not enter into the calculation. For example, pregnant women had a mean intake of total water from milk and milk drinks of 308 g/day (Table 4), but their mean intake of milk *per se* would be a slightly higher figure. The presence of zeros in the 50th percentile column indicates that at least half of the women in that particular group consumed essentially no legumes, nuts or seeds, fruit juice, tea, coffee, soft drinks, or alcoholic beverages over the three days of the study.

Considerable individual variation is demonstrated by the marked differences in intake between the mean, median, and 95th percentiles. For example, the average coffee and tea intake of our subjects was not especially high. Table 4 shows that mean intake for pregnant women was 132 g water/day in tea and 197 g water/day in coffee, whereas lactating women consumed, on average, 253 g water/day in tea and 205 g water/day in coffee (an 8-oz cup = 240 g water). The even lower 50th percentile values indicate that many of the women did not consume any tea or coffee at all. Nevertheless, a small fraction of subjects, representing the top 5 percent of

intake (i.e., the 95th percentile), drank nearly one liter per day of caffeinated beverage.

Sources of tapwater are shown in Table 5. Nearly all the tapwater consumed was provided by a small number of dietary items: drinking water; coffee; tea; grain and grain products; and fruit juices. (Carbonated beverages, most alcoholic beverages, and many fresh foods do not contain tapwater in the first place.) In contrast, a larger range of foods and beverages served as substantial sources of total water (Table 4).

Reproductive status had little effect on the relative contribution (expressed as the population proportion[10]) of drinking water, beverages, and foods to intake of total water (Table 4). For control, pregnant, and lactating women, respectively, the contribution to total water intake was 30 percent, 34 percent, and 30 percent for drinking water; 46 percent, 43 percent, and 45 percent for other beverages; and 24 percent, 23 percent, and 25 percent for foods.

Sources of tapwater intake varied more with reproductive status (Table 5). Drinking water contributed a larger fraction of the tapwater intake of pregnant women (58 percent) than for either control women (50 percent) or lactating women (52 percent). Other beverages accounted for a population proportion of 34 percent, 43 percent, and 41 percent of the tapwater intake of pregnant, control, and lactating women, respectively. Only 7 percent of the tapwater intake of our study participants was contributed by solid foods.

Discussion

By providing population-based estimates of total water and tapwater intake by pregnant and lactating women, our study addresses a nearly complete lack of information on this topic. Recent national surveys of tapwater use in Great Britain[12] and Canada[13] did not present data for pregnant or lactating women. Studies conducted by the California State Department of Health on the relationship of pregnancy outcome and water exposure did not evaluate quantities of water consumed from all sources.[14] A clinical study of fluid intake during lactation was very thorough but was conducted in a single locale (Iowa) using 26 self-selected volunteers.[1,15]

Our estimates derive from a relatively large final analytic sample that included 188 pregnant women and 77 lactating women. NHANES II,[16] which also used a stratified random national sampling design, included even fewer pregnant (n = 122) and lactating (n = 41) women than the 1977–78 NFCS. Larger numbers of pregnant and lactating participants would be desirable but cannot

readily be obtained without expensive oversampling procedures.

We think it unlikely that our estimates of water intake are affected by serious non-response bias. The overall household response rate for the 1977–78 NFCS was 72 percent, very similar to the 73 percent individual response rate obtained for NHANES II,[11] and nearly all eligible individuals (94 percent) within participating NFCS households agreed to participate in the individual intake surveys as well. Furthermore, dietary data are probably no more susceptible to bias than other types of health information, and NHANES II investigators found no indication of household non-response bias for health-related variables.[11] In addition, there is no evidence that water intakes of persons with complete data differed systematically from intakes of persons lacking complete data. We thus consider our analytic sample to be representative of the surveyed study groups.

How reproducible (i.e., reliable) and accurate (i.e, valid) are our estimates? Few other data are available, but our estimates compared favorably with them. Median intake of at-home drinking water (plain tapwater) by pregnant women interviewed by the California Department of Health was 2–3 cups per day,[14] very similar to our finding that median drinking water intake of pregnant women was 640 g (2.7 cups) per day (Tables 4 and 5). The lactating women in our study had an average total water intake per unit of energy (1.3 g/kcal/day; Table 2) similar to that reported by lactating women in the Iowa study (1.4 g/kcal/day)[2] and in both studies two-thirds of the participants consumed more than the recommended 1 g/kcal.[1] As expected, our larger national sample of lactating women had a wider range of total water intake values (1,087–4,159 g/day), which completely encompassed the range for the 26 Iowa participants (1,920–3,957 g/day).[2] Both our study and the Iowa study found the highest level of total water intake to be approximately 4 liters (4,000 g) per day.

The non-pregnant, non-lactating control women in our study had a mean intake of total water from beverages (1,480 g/day; Table 4) very similar to that of adult British women (1.5–1.6 L/day).[12] Intake of tapwater from beverages (1,081 g/day; Table 5) also was very similar to that of British women (1.0–1.1 L/day).[12] Canadian women, on the other hand, consumed relatively more tapwater-based beverages (1.3–1.6 L/day).[13]

As the comparisons above indicate, our results are generally compatible with other published data despite differences in study population, intake methodology, and sample size. It is possible, however, that our estimates are on the low side. Using three days' worth of data for each participant would presumably allow the under-reporting biases of 24-hour recalls and the over-reporting biases of dietary records to balance out.[6,17] Nevertheless, energy intakes reported by NFCS participants were lower than expected and were very similar to the energy intakes yielded by the single 24-hour recall used in the NHANES II survey.[18] Under-reporting of food intake thus may account for the lower mean total water intake of our lactating study subjects (2,242 g/day, Table 2) compared with that of the Iowa participants (2,860 g/day).[2] Alternatively, the diets of the highly educated Iowa participants may not have been representative of lactating women's diets in general. The Iowa participants were studied as part of an attempt to increase milk production by deliberately increasing fluid intake,[15] and they may have been consuming extra fluid even during the baseline phase of the study.

How timely are the estimates? The data used for this analysis were collected in 1977–78. In the last decade there have been important changes in certain aspects of the food supply, including increased purchase and consumption of meals outside the home and greater intake of carbonated soft drinks.[19] Unfortunately, the USDA's more recent Continuing Survey of Food Intake by Individuals[19] did not collect information on intake of plain water (i.e., drinking water), and data from these surveys therefore cannot be used to derive either tapwater or total water intake.

Our population-based cross-sectional study confirms that pregnancy and lactation are associated with significant increases in water intake, although a prospective study design is needed to evaluate whether water intake increases spontaneously with the onset of pregnancy and lactation. The estimated theoretical increase in water requirement caused by lactation is 0.5–1.0 L/day[1,20] but in our study the mean daily total water intake of lactating women was only 302 g (i.e., 302 ml) higher than the total water intake of control women (Table 2). The non-pregnant, non-lactating control women in our study consumed quantities of total water well above the minimum amount needed to prevent dehydration. This implies that many if not most women may not need to increase their water intake when they become pregnant or begin to lactate, because their pre-pregnancy intakes were already more than adequate. Unnecessary recommendations to consume "lots of fluids" might inspire some women to replace nutritionally valuable solid foods with water or other nutrient-free beverages such as tea, coffee, or diet soda. Dietary counseling might be better directed towards the few women who habitually consume very small amounts of liquid.

Our evaluation of the relative contribution of various dietary sources to total water and tapwater intake has implications for questionnaire design. Studies of water consumption can be conducted more efficiently by limiting questions to the most important sources. We found that drinking water, coffee, and tea alone accounted for a population proportion[10] of 87 percent of tapwater intake by our study participants (calculated as the sum of source-specific means divided by the all-sources mean, Table 5). Adding reconstituted fruit juices and cooked grain products (such as rice, hot cereal, noodles, pasta) to this list brings this figure to 94 percent. A nearly complete assessment of the quantities of tapwater consumed could thus be made using a relatively short questionnaire. A longer list of sources (Table 4) would be needed to assess total water intake by questionnaire.

We found that women living in rural areas and in the western or southern regions of the United States consumed more total water and tapwater than women living in urban/suburban areas in the northeast and midwest. This could reflect differences in climatic temperature and humidity, physical activity, and diet, particularly beverages. Estimates of intake of water-borne elements might be improved by taking these residential factors into account. Season, on the other hand, was responsible for less variation, probably due to climate control and alternation throughout the year of hot and cold drinks. Similar minor effects of season were observed in Canada, where tapwater intake was slightly (5–10 percent) higher in the winter.[13] The Iowa study[2,15] also found that total water intake by lactating women was minimally affected by season.

Our findings may be used to estimate intake of minerals via tapwater. Calcium is of particular interest because of the very high demands imposed by reproduction; the Recommended Dietary Allowance (RDA) for calcium for most adult women is 800 mg/day, whereas for pregnant and lactating women the RDA is 1,200 mg/day.[1] The calcium content of home water supplies averages 50–60 mg/L, although in hard water areas the concentration may reach 145 mg/liter.[21] In the typical situation, pregnant or lactating women ingesting 1.2–1.3 liters/day of tapwater (Table 3) from the home supply would take in by this route only 60–80 mg/day of calcium, or about 5 percent of the 1,200 mg recommended daily allowance. Only the women living in areas with very hard water (145 mg/L) and drinking unusually large quantities of this hard water (2.2–2.4 L/day; 95th percentile of intake; Table 3) would obtain an appreciable amount of calcium from the tap.

Estimates of exposure to toxic metals and chemicals in tapwater often are made with the assumption that few persons consume more than 2 liters per day[21–24]. Canadian researchers found that 12 percent of adults consumed 2 liters or more of tapwater daily.[13] In our study 10 percent of the non-pregnant, non-lactating women, 8 percent of the lactating women, and 15 percent of the pregnant women consumed 2,000 g/day or more of tap water (see "Results"), and 3–4 percent consumed 2,500 g or more. This suggests that 2 liters/day might not be a sufficiently high estimate of intake to protect 95 percent of these susceptible population groups, particularly pregnant women, from water-borne toxic substances unless a sufficient margin of safety is incorporated into estimates of exposure. ☐

Regression-Adjusted Small Area Estimates of Functional Dependency in the Noninstitutionalized American Population Age 65 and Over

Jennifer M. Elston, MHSA, Gary G. Koch, PhD, and William G. Weissert, PhD

ABSTRACT

Health planning efforts for the population age 65 and over have been hampered continually by the lack of reliable estimates of the noninstitutionalized long-term care population. Until recently national estimates were virtually nonexistent, and reliable small area estimates remain unavailable. However, with the recent publication of several national surveys and the 1990 Census, synthetic estimates can be made for states and counties by using multivariate methods to model functional dependency at the national level, and then applying the predicted probabilities to corresponding state and county data.

Using the 1984 National Health Interview Survey's Supplement on Aging and the 1986 Area Health Resources File System, we have produced log-linear regression models that include demographic and contextual variables as predictors of functional dependency among the noninstitutionalized population age 65 and over. Age, sex, race, and the percent of the 65 and over population who reside in poverty were found to be significant predictors of functional dependency. Applying these models to 1986 Medicare Enrollment Statistics, regression-adjusted synthetic estimates of two levels of functional dependency were produced for all states and—as examples of how the rates can be used to produce additional synthetic estimates—the largest county in each state. We also produced point estimates and standard errors for the national prevalence of functional dependency among the noninstitutionalized population age 65 and over. (*Am J Public Health* 1990;81:335–343)

Introduction

Bivariate correlates of functional dependency suggested in previous work include age,[1–11] being female,[3,4,6–10,12] being of a race other than White,[3,10] being unmarried or residing with family members,[6,7,10] living alone,[13] having a low income,[7,10,11] and being at the low end of the social class continuum.[7] However, Feller[1] found no significant difference in rates of dependency by gender; Dawson, Hendershot, and Fulton[5] found gender differences to disappear when age structure was taken into account; and Jette and Branch[13] found that among those who lived with others, level of income was inversely related to increasing disability.

A few researchers have also investigated the relationship of functional dependency to other factors with the use of multivariate methods. Among these age,[10,14,15–17] physical performance,[10,14] number of chronic conditions,[14,15] sex,[14] race,[14] emotional performance,[14] health status,[14] prior functional abilities,[10] social class,[15] income,[15] and education[16] have been shown to be significantly related to level of functional dependency.

Yet, health planning efforts for the population age 65 and over continue to be hampered by the lack of reliable data and methods for making population-based estimates at subnational levels. Unger and Weissert's[17] research, which used 1977 data to produce synthetic estimates of the functionally dependent noninstitutionalized age 65 and over population, was forced to rely upon a data set with much more limited measures of dependency than those available on more recent national surveys.

Although several methods exist to produce synthetic estimates, none has been found to be uniformly superior. One well suited method uses a fitted regression model to predict outcomes from correlates of the trait or characteristic of interest. This approach has been widely used.[17–29]

This paper presents log-linear regression models as well as regression-adjusted synthetic estimates of the noninstitutionalized dependent age 65 and over population in each state and its largest county. With appropriate caution the rates generated by the models can be applied to the number of noninstitutionalized age 65 and over individuals in various age, sex, race, and poverty subgroups living in other counties to produce synthetic estimates of the prevalence of dependency for those counties.

Methods

Data Sources and Definitions

Data were drawn from the 1984 National Health Interview Survey's Supplement on Aging, the 1986 Area Resource File System, *State, Regional, and Na-*

tional Monthly and Seasonal Heating Degree Days,[30] and 1986 Medicare Enrollment Statistics.

The 1984 Supplement on Aging, based on a multistage area probability sample, provides self-reported characteristics (such as conditions and impairments, living arrangement, and functional abilities) for 11,497 civilian noninstitutionalized people age 65 and over. A more detailed description of the survey is provided by Fitti and Kovar.[31]

Contextual variables were drawn from two sources: the 1986 Area Resources File System and *State, Regional, and National Monthly and Seasonal Heating Degree Days*. The 1986 Area Resource File System is a county-specific data base containing more than 7,000 variables concerning a wide range of social, economic, and health resource characteristics, and is described in detail elsewhere.[32] The use of one additional contextual variable, heating degree days (which is available from the National Oceanic and Atmospheric Administration) was examined.

Using the geographic identifiers available on the 1984 Supplement on Aging, corresponding contextual variables from the above two sources were attached at the Standard Metropolitan Statistical Area (SMSA) for individuals residing in one of 31 large self-representing SMSAs. Individuals on the data set who resided outside these 31 areas were assigned the corresponding regional (northeast, north central, south, or west) and urbanity (SMSA or nonSMSA) average for their type of residence. The result was 39 distinct geographic areas: 31 self-representing SMSAs, and four urban and four nonurban regional areas.

Synthetic estimates are produced by multiplying the regression-adjusted national rates by population data. Because any explanatory variable included in the national model must also be available in the small area population data, Medicare Enrollment Statistics were used for small area population data. Enrollment data by age, sex, and race for each state and county in the United States are available from the Bureau of Data Management and Strategy at the Health Care Financing Administration.[33]

Model Specification

Unit of Analysis

The unit of analysis for this study was the individual participant in the 1984 Supplement on Aging. Although the weighted sample size of the 1984 Supplement on Aging is over 26 million, we normalized the provided survey weight variable to sum to the actual sample size of 11,497 so as not to exaggerate significance levels in model evaluation.

Dependent Variable

The dependent variable for our analysis was a three level hierarchical measure which classified individuals into their highest level of dependency defined as follows.

ADL Dependent: Individuals residing in the community who, because of a health or physical problem, reported that at the time of the survey they had difficulty with and received human assistance with eating, transferring, toileting, dressing, or bathing.

Mobility/IADL Dependent: Individuals residing in the community who, at the time of the survey, were not ADL dependent, but because of a health or physical problem reported difficulty with and received human assistance with inside mobility, outside mobility, meal preparation, grocery shopping, money management, housework (light and heavy), or telephone usage.

Independent: Individuals residing in the community who, at the time of the survey, were neither ADL nor IADL dependent.

Explanatory Variables

Coupling the constraints of the Supplement on Aging and Medicare county data, the following explanatory variables were available for use:

- Sex (coded 1 if female and 0 if male);
- Race (coded 1 if other and 0 if White);
- Age Group (coded as a zero-centered variable equal to the midpoint age in five-year intervals from 65 to 85 and over minus 77.5, divided by 5, i.e. −2, −1, 0, 1, or 2);
- Age-Squared (coded as the square of the "age group" variable, i.e. 4, 1, 0, 1 or 4); and
- Pairwise Interactions (coded as the product of the pair).

In addition, a number of contextual variables were hypothesized to affect the rate of functional dependency among the noninstitutionalized population age 65 and over. These included:

- the number of nursing home beds per 1,000 population age 65 and over;
- the number of unoccupied nursing home beds per 1,000 people age 65 and over;
- the number of acute care hospital beds per 1,000 people age 65 and over;
- the per capita income of the population;
- the percent of the persons age 65 and over who reside in poverty;
- the number of primary care physicians per 1,000 persons age 65 and over;
- the percent of the poverty population that is covered by Medicaid;
- the age-adjusted mortality rate;
- the population per square mile;
- the population age 65 and over per square mile;
- the percent of the population that resides in an urban area; and
- heating degree days (the annual number of degrees of heating or cooling which would be required to move an area's temperature one degree for one day toward 68 degrees Fahrenheit).

Each of the contextual variables was evaluated for entry into the models both continuously and categorically. For the categorical analysis the variables were collapsed into three levels: high, medium, and low—coded −1, 0, and 1, respectively.

Statistical Methods

Given the multinomial nature of the dependent variable, a multicategory extension of logistic regression which provides a general structure was used. (The structure imposed on the data by an ordered logistic regression model was evaluated and found to be inappropriate.) The log-linear model was fit using a SAS supported procedure designed for categorical data modeling, PROC CATMOD.[34] For log-linear model analysis, CATMOD uses maximum likelihood estimation. Given the three category dependent variable, two sets of parameter estimates were produced: one for the logged ratio of not dependent to ADL dependent, and one for the logged ratio of IADL dependent to ADL dependent. Working with these two equations simultaneously yielded a formula for each category of the dependent variable: 1) not dependent; 2) IADL dependent; and 3) ADL dependent.

Because failure to account for the complex sampling design of surveys such as the Supplement on Aging can lead to underestimated variances of the regression coefficients, the magnitude of the design effects was tested with RTILOGIT.[35] Results confirmed previous findings that design effects on the Supplement on Aging

TABLE 1—Regression Results: Predictors of Functional Dependency among the American Noninstitutionalized Age 65 and Over Population[a]

	Log (Prob. not dependent/ Prob. ADL dependent)		Log (Prob. IADL dependent/ Prob. ADL dependent)

[b] $p < .001$

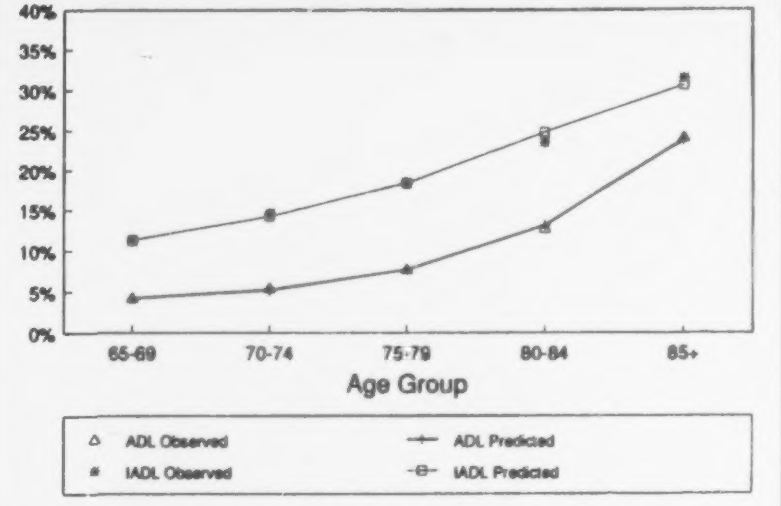

FIGURE 1—Observed and Predicted ADL and IADL Dependency Rates

are relatively small,[31] and estimates produced by complex sample methods such as RTILOGIT would not alter results or conclusions.

For model testing, the data base was randomly divided in half within each primary sampling unit. In the first half of the data base candidate models were fit for the dependent variable. Once model development was completed, the goodness-of-fit of the model was validated in the other half of the data base as described in the Appendix.

Results

Direct Estimates

Direct estimates from the 1984 Supplement on Aging show that in 1984 approximately 2.0 million (7.3 percent) of the noninstitutionalized population age 65 and over in the United States suffered from at least one ADL dependency, and an additional 4.2 million (16.4 percent) suffered from at least one IADL dependency. National prevalence and percentage estimates by race, sex, and age and their accompanying standard errors are presented in Appendix Tables A1-A4.

Regression-Adjusted Results

Table 1 presents the survey-weighted results of the log-linear regression analysis. Five variables were selected to form the final model: race, sex, age, age-squared, and one contextual variable, the categorical variable reflecting the percent of the population age 65 and over who reside in poverty. Each was a significant predictor of functional dependency in the overall model.

Other contextual variables were eliminated from the model. Three of these variables (when entered as the sole contextual variable in the model) had p-values $< .02$ (the number of heating degree days, the ratio of Medicaid recipients to the population below poverty, and the number of unoccupied nursing home beds per 1,000 elderly). However, all p-values became nonsignificant ($p > .05$) when entered in the model in combination with the poverty variable.

While theoretical considerations would argue for inclusion of these and the other contextual variables in the model, inclusion complicates the calculation of synthetic estimates. Since the goal of our study was to provide a practical and easily administered tool for producing synthetic estimates we elected to omit nonsignificant variables from our model.

Similarly, although the continuous form of the poverty variable might seem preferable from a statistical perspective, differences in conclusions between the continuous and the categorical form of the variable were negligible, and as results and examples could more easily be presented with the categorical variable, results presented are for the latter.

The fit of this model was evaluated with the log-likelihood ratio chi-square statistic. Since the statistic was nonsignificant, the use of the model was supported. The need for pairwise interactions of the variables was evaluated and determined to be unnecessary.

Further evaluation of the fit of the model was done as described in the Appendix, and by plotting the observed age-specific rates of dependency and the regression-predicted rates of dependency. Both ADL and IADL predicted rates closely approximate the observed rates (Figure 1). However, when the population

All Others	Male	7.0	8.5	12.5	20.7	35.9	11.4
	Female	7.1	8.4	11.8	18.4	30.2	11.3
	Both	7.1	8.5	12.0	19.0	32.3	11.3
All Races	Male	5.2	6.4	9.7	16.4	30.6	8.9
	Female	5.5	6.7	9.5	15.5	26.7	9.4
	Both	5.3	6.6	9.6	15.8	28.0	9.2

is divided into smaller subgroups, such as females of a race other than White, the model fits somewhat less well, but this could be due to the greater variability in those cases from reduced sample size.

Table 2 presents regression-adjusted estimates of the prevalence of ADL dependency, and Table 3 of IADL dependency. Because the poverty variable has three values—less than 8 percent (low); between 8 and 15 percent (moderate); and over 15 percent (high) of the population age 65 and over residing in poverty—three sets of estimates were produced.

Results showed the relative likelihood of both ADL and IADL dependency increases quadratically with age, is higher if of a race other than White, and increases with an increasing percent of the population age 65 and over residing in poverty. The likelihood of IADL dependence is higher if female, but the relative likelihood of being ADL dependent if female varies across age, race, and poverty groups. Although it is in general higher for females than males until age 80 in communities of low and moderate levels of poverty, and until age 75 for those in high poverty communities, after these ages the percent of noninstitutionalized males with an ADL impairment is either equal to or greater than that of females.

Regression-Adjusted Synthetic Estimates

Although Medicare Enrollment Statistics were the best available population data, two adjustments had to be made. First, because approximately 5 percent of the population age 65 and over is not enrolled in Medicare, the numbers were inflated to reflect the total population age 65 and over. The percent of the population age 65 and over enrolled in Medicare varies little across sex or family income groups, but does differ across race groups,[36] therefore the number of White Medicare enrollees was inflated by 4.4 percent, and the number of all other enrollees was inflated by 13.5 percent.

Second, because Medicare Enrollment data include both the noninstitutionalized and institutionalized age 65 and over population, and rates produced from our analysis are applicable for the noninstitutionalized population only, the numbers therefore were deflated to remove the noninstitutionalized age 65 and over population.

Using the 1985 National Nursing Home Survey and the 1985 National Health Interview Survey, a logistic regression equation was produced to estimate rates of institutionalization among the age 65 and over population at the national level. Candidate explanatory variables for inclusion in the model included those available on the merged data set for which corresponding population data existed. Given this constraint, age (in five-year intervals from 65 to 85 and over), sex, race (White and all others), and geographic region (northeast, north central, south, and west), as well as their pairwise interactions and transformations were available for use. Region was included because the supply of nursing home beds varies geographically.[37] The model found to best fit the data included age, age-squared, sex, and an indicator variable reflecting whether or not the individual resided in the north central region of the country. Estimates produced from the model were used to deflate the state and county population data to be representative of the noninstitutionalized age 65 and over population (results are available from the authors).

By applying the regression-adjusted rates of dependency to the adjusted Medicare data, synthetic estimates of the functionally dependent noninstitutionalized age 65 and over population were produced for each state, and the largest county in each state (Tables 4 and 5).

These estimates are based upon three assumptions. First, that the race, sex, age, and poverty-specific disability rates from the 1984 Supplement on Aging did not change between 1984 and 1986. Second, that the relationship between dependency and race, sex, age, and the percent of the population age 65 and over residing in poverty is the same for each state and its largest county as it is for the nation. And third, that race, sex, age, and the percent of the population age 65 and over residing in poverty are the only important predictors of functional dependency. Thus, the estimates will err to the extent that the relationship between dependency and race, sex, age, and poverty in a community has changed over time; the extent that the relationships vary from national averages; and the extent to which other known or unknown factors

TABLE 3—Percentages of IADL Dependent Americans Age 65 and Over Living in the Community by Age, Sex, and Race: Regression-adjusted Estimates

	Both	13.1	16.2	20.7	27.1	31.6	18.3

which are not in the model strongly influence functional dependency.

Discussion

Using log-linear models, regression-adjusted synthetic estimates of the rates of two levels of functional dependency among the noninstitutionalized age 65 and over population were produced. Age, sex, race, and the percent of the population age 65 and over who reside in poverty were found to be significant predictors of ADL and IADL dependency among the noninstitutionalized population age 65 and over.

Introduction of a contextual variable into the regression model appears overdue given that estimated rates are substantially affected by the poverty variable. The results here, which are consistent with other researchers' work, suggest that just as poverty is a strong correlate of many unwanted problems in youth and adulthood, so too its sequelae are present in old age, manifesting as higher dependency rates.

Results here also confirm the strong relationship reported by other researchers between dependency and age, as well as the variation in age-specific rates of dependency between men and women, and Whites and all other races. While explication of the underlying determinants of these variations is beyond the scope of this paper, reconfirming their importance suggests the need for policies and research agendas sensitive to these relationships and variations. Of particular importance is the quadratic relationship between age and dependency, meaning that with each passing five-year interval rates of dependency increase at an increasing rate—a sobering prospect given the rapid expansion of the oldest old population.

The percentages generated with the regression models (Tables 2 and 3) can be multiplied by corresponding population estimates for specific geographic areas of interest to generate regression-adjusted synthetic estimates of dependency (similar to those in Tables 4 and 5) among the noninstitutionalized age 65 and over population.

Such estimates are likely to be most useful as a gauge of the size of the long-term care population in subnational areas. They may also be of use as initial building blocks for estimating demand for formal long-term care services. While functional dependency estimates will not translate directly to service demand without other important measures (i.e. income, price, preferences, and other need measures such as social support), previous research has shown that utilization of formal health care services is closely related to need.[38,39] Furthermore, the usefulness of the methods outlined here will be greatly enhanced by the 1990 US Census, which will make age, sex, race, and poverty data widely available.

Finally, it should be noted that while the analysis supports the use of these equations to produce small area estimates of functional dependency among the noninstitutionalized age 65 and over population, the quality of the small area estimates produced by them still needs to be evaluated in future research using geographic indicators (not presently available for public use) which permit comparison of synthetically produced estimates with direct estimates from adequately large samples for the same small areas. □

Acknowledgments

The authors acknowledge the assistance of Laurie McVey and Ali Barakat for their help with the literature review, Jane Darter for programming, and Mary Grace Kovar for helpful comments.

This study was funded by the office of the Assistant Secretary for Planning and Evaluation of the United States Department of Health and Human Services and by the Pew Memorial Trust of the Pew Charitable Trusts. Opinions expressed are those of the authors only. An earlier version of this paper was presented at the 116th Annual Meeting of the American Public Health Association in Boston, Massachusetts, November 1988.

APPENDIX

To assess goodness-of-fit the model was first applied to the second half of the data set, and its goodness-of-fit was evaluated with the chi-square statistics associated with the individual parameters and with the lack-of-fit statistic.

Second, the model was applied to the entire sample to test the fit of the estimated coefficients. This was done by including an indicator variable representing the half of the data set from which each observation came, as well as all of its pairwise interactions with the other variables in the model.

Third, goodness-of-fit of the model was evaluated by comparing the similarity of the model-predicted dependency rates with their observed counterparts in the other half of the data set. In so doing, the candidate models were used to determine the predicted values of the probability of dependence for individuals in the other half of the data base. The differences between these predicted values and their true value gives a residual value for that individual. The closeness of the averages of the residuals to zero for various subgroups of individuals (e.g. males, females, different age groups, etc.) and lack of correlation of the residuals with characteristics of individuals are indicative of goodness-of-fit. In addition, Pearson correlations were evaluated for the residuals and each of the explanatory variables, and their low values supported the fit of the model.

TABLE A-1—Direct Point Estimates of the Number of Noninstitutionalized Americans Ages 65 and over Who Were Functionally Dependent in 1984 by Age, Sex, and Race

[a] Personal care dependent includes bathing, dressing, toileting, transferring, or eating. Individuals classified as personal care dependent may also be dependent in mobility or household activities but are counted only as personal care dependent.

[b] Mobility or household activity includes inside mobility, outside mobility, meal preparation, grocery shopping, money management, housework (heavy and light), and telephone usage. Individuals already classified and counted in this table as personal care dependent are excluded from this category.

Dioxins and Dibenzofurans in Adipose Tissue of US Vietnam Veterans and Controls

Han K. Kang, DrPH, Kevin K. Watanabe, MS, Joseph Breen, PhD, Janet Remmers, MS, Margaret G. Conomos, MPH, John Stanley, PhD, and Michele Flicker, PhD, MD

ABSTRACT

The primary reason for concern about the adverse effects of exposure to Agent Orange is attributable to its toxic contaminant, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) or dioxin. We studied adipose tissues from 36 Vietnam veterans, a similar group of 79 non-Vietnam veterans, and 80 civilians; the tissue specimens were selected from the 8,000 archived tissues collected from the non-institutionalized general population by the US Environmental Protection Agency. The geometric mean (± standard deviation) dioxin levels in adipose tissue for Vietnam veterans, non-Vietnam veterans, and civilian controls were 11.7 (±1.7), 10.9 (±1.7), and 12.4 (±1.9) parts per trillion on a lipid weight basis, respectively. The mean levels for these groups were not significantly different from each other with or without adjustment for age of individuals, body mass index, and specimen collection year. In addition, none of the surrogate measures of Agent Orange exposure such as military branch, service within specific geographic region, military occupation, and troop location in relation to recorded Agent Orange spray was associated with the dioxin levels in adipose tissue of Vietnam veterans. Our results suggest that heavy exposure to Agent Orange or dioxin for most US troops was unlikely. (*Am J Public Health* 1991; 81:344–349)

Introduction

From 1965 to 1970, the US Air Force sprayed more than 40 million liters of Agent Orange in South Vietnam.[1] Approximately two million American soldiers served in Vietnam during this period. Agent Orange was the name used for a phenoxy herbicide consisting of a mixture of 2,4-dichloro-phenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). The 2,4,5-T contained 1-50 parts per million of the contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), also known as dioxin. Dioxin is extremely toxic in laboratory animals, promotes liver tumors in rats, and is teratogenic in mice.[1,2] The two parent herbicides, 2,4-D and 2,4,5-T are very short-lived in the human body and do not persist in the environment.[3] Because of these characteristics and their relatively low toxicity in humans, attention has been focused on the highly persistent and toxic chemical, dioxin.

Many Vietnam veterans believe that they were heavily exposed to Agent Orange and that the exposure is responsible for health problems such as skin rashes, rare types of cancer, and birth defects of their children. Since 1979, 200,000 Vietnam veterans have come to Department of Veterans Affairs (VA) hospitals for an Agent Orange Registry medical examination because of concerns about exposure to Agent Orange.

Two questions are paramount in dealing with the veterans' concerns. The first is whether dioxin causes birth defects, immune deficiencies, cancers, or other chronic health problems in humans. The second is whether Vietnam veterans, in general, received substantial exposure to dioxin while they served in Vietnam. This study addresses the second question.

Dioxin accumulates preferentially in the body fat of animals and man. Its half-life in humans is estimated at five to 11 years.[4-7] Among the many 2,3,7,8-substituted polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) found in the environment and in samples of human adipose tissue, only 2,3,7,8-TCDD or dioxin was present in Agent Orange.[7] Dioxin levels in adipose tissues could, therefore, serve as a biological marker of exposure to Agent Orange. In fact, several studies have reported that even after approximately 20 years, dioxin levels were elevated markedly in the adipose tissue or blood serum of Vietnam veterans who handled Agent Orange.[6-8] More recently, however, the Centers for Disease Control (CDC) reported that current serum dioxin levels of Army Vietnam combat troops did not differ significantly from those of non-Vietnam veterans and that dioxin levels in Vietnam veterans did not increase with increased exposure levels estimated from military records.[9] This study was criti-

cized on the basis that blood specimens taken almost 20 years after exposure could not represent what happened in Vietnam and that veterans selected for the study were limited to Army enlisted men who served in only one geographic region of Vietnam.[10]

The purpose of our study was twofold: 1) to determine if a group of individuals with military service in Vietnam have significantly higher levels of dioxin in adipose tissue than either a similar group of non-Vietnam veterans or civilian peers, and 2) to determine if dioxin levels in adipose tissue were associated with specific demographic and military service characteristics.

Methods

Selection of Study Subjects

Our study used adipose tissue specimens that had been collected from the general population by the US Environmental Protection Agency (EPA). The EPA has conducted the National Human Adipose Tissue Survey (NHATS) since 1970 to monitor the human body burden of pesticides and other selected chemicals. Up to 1,000 adipose tissue specimens have been collected annually from pathologists and medical examiners across the country and analyzed by the EPA for the selected chemicals. After analysis, the unused tissue specimens were sent to a central facility to be stored at 0°C to −20°C.

The NHATS utilized a probability sample of the Standard Metropolitan Statistical Areas (SMSA) that is designated to represent a sample of the US population in terms of age, sex, and race.[11] The target population for the NHATS program was all non-institutionalized persons in the conterminous US. However, due to the invasive nature of collecting adipose tissue samples, the sampling population was limited to individuals who died from external causes (90 percent) and surgical patients (10 percent). Within each SMSA, hospitals or medical examiners were identified and asked to contribute tissue specimens according to the design specifications of age (0–14 years, 15–44 years, 45+ years), sex and race (White, non-White). Since the vast majority of Vietnam veterans were men born between 1936 and 1954, this study was restricted to specimens from men born in that period.

An Inventory File was created for the 8,000 specimens that were recorded to have an adequate amount of tissue. It was found that 528 of 8,000 specimens were from males born between 1936 and 1954. The hospitals or medical examiners who originally collected the 528 specimens were recontacted to obtain enough identifying information on the donors to determine their military service status. The collection effort yielded information for 494 or 94 percent of the 528 specimens.

The military service status for these 494 men, including any Vietnam service, was determined by reviewing records archived at the National Personnel Records Center (NPRC) in St. Louis and military records maintained at other locations. From this effort, 134 men (or 27 percent of 494) were initially found to have served in the military, 40 of whom served in Vietnam. According to the 1980 Census, one would expect about 34 percent of men in this age group to be veterans. All 40 Vietnam veterans were selected for the study. From the 94 remaining veterans, 80 were selected randomly for the non-Vietnam comparison group. Two civilians were closely matched to each Vietnam veteran by birth year (±two years) and sample collection year (±two years). Age and sample collection year were considered important matching variables because of probable accumulation of dioxin in the body with each year of exposure and the possibility of degradation of fat or dioxin while in storage. All adipose tissue specimens were analyzed during 1987. Demographic data were taken from the NHATS file and the official death certificates. Body mass index (BMI) was calculated from weight and height as follows: BMI = weight in Kg/height in m^2.

Determination of Opportunity for Agent Orange Exposure

A precise estimate of the exposure of each Vietnam veteran to Agent Orange is not considered feasible based on either military records or self-reported data. In this study the probable opportunity for exposure was determined from the following: branch of service, military occupational specialty code (MOSC), and location of the individual's unit in Vietnam in relation to recorded Agent Orange spray. Ground troops in Vietnam might have had a higher probability of contact with Agent Orange than other Vietnam veterans due to the nature of their military operations. Ground troops engaged in combat were assumed more likely to be in herbicide-sprayed areas. As another surrogate for exposure, a veteran's military unit was assigned to one of the four broad military regions in Vietnam. According to the records of the US Air Force Ranch Hand Operation, 20 million liters of Agent Orange were sprayed in Military Region III from 1965 to 1970. During the same period, Military Regions II, I, and IV received 9.5, 8.3, and 4.5 million liters, respectively. Finally, troop locations (company size units) were determined on a 100-meter grid map of Vietnam at intervals of 90 days or less. Computer matching of troop location with respect to time and distance from recorded herbicide spray tracts was carried out using the HERBS tape and services HERB tape databases. The HERBS tape contained information on most of the herbicide missions flown by fixed-wing aircraft from 1965 to 1971, and on crop destruction missions flown by helicopter between 1968 and 1971. The tape contained information on the type of herbicide, gallons, dates, and where spray runs started and ended. Services HERBS Tape prepared by US Army and Joint Services Environmental Support Group identified and documented an additional six million liters of herbicide sprayed mainly by Army personnel around the perimeter of base camps, fire bases, air bases, and other fixed military installations. The opportunity for Agent Orange exposure was determined in two ways: an individual's company was ever located either within two kilometers (km) of a recorded Agent Orange spray tract within three days of application or within eight km of a spray tract within 90 days application.

Laboratory Analysis

Specimens from the three groups were assigned randomly to one of 20 batches. Each batch typically consisted of 10 study specimens and four quality control (QC) samples. The QC samples provided data on method accuracy and precision. In addition, the external quality control audit samples were prepared by another laboratory and incorporated as blind samples into the various batches. Study specimens and QC samples were coded with a unique laboratory number and submitted to the analysts as blind samples. Following sample cleanup and preparation, instrumental analyses were achieved using a high resolution gas chromatograph coupled to a high resolution double-focusing mass spectrometer. Overall method accuracy and precision for 2,3,7,8-TCDD analyses of spiked lipid samples were 113 percent recovery and 8.8 percent coefficient of variation.

The analytical protocol provided for the detection and quantitative determination of 17 congeners of 2,3,7,8-substituted

TABLE 1—Distribution of 2,3,7,8-TCDD Levels in Adipose Tissue by Military Service Status, in pg/g of the Total Extractable Lipid (ppt)

Status	N	Arithmetic Mean ± SD[a]	Geometric Mean	Percentile 25th	 50th (median)	 75th	 90th	 95th
Vietnam Veterans	36[b]	13.4 ± 7.4	11.7	7.8	10.0	17.3	26.8	30.4
Non-Vietnam Veterans	79[c]	12.5 ± 7.2	10.9	7.6	11.4	14.8	19.8	25.3
Civilians	80	15.8 ± 14.5[d]	12.4	7.9	11.8	18.0	30.5	43.4

[a] Standard deviation

[b] Four of the 40 men initially classified as having served in Vietnam were excluded from analysis because two veterans' specimens had less than 20% extractable lipid content, one veteran did not have adequate amount of tissue for analysis, and one veteran served only in Thailand.

[c] One of the 80 men initially classified as having served in the military was excluded because his military service could not be documented unequivocally.

[d] The large standard deviation was attributed to an outlier with a value of 106. The value was verified. The occupational history of this individual is unknown. He was listed as a "laborer" on his death certificate. Analysis conducted without this value resulted in an arithmetic mean of 14.7 (± 10.3) and a geometric mean of 12.2. There was still no statistically significant difference between the groups (p = 0.49).

polychlorinated dibenzo-p-dioxins (PCDD) and dibenzofurans (PCDF). The minimum measurable concentration ranged from 1 picogram per gram (pg/g) for 2,3,7,8-TCDD and 2,3,7,8-TCDF, to 5 pg/g for OCDD and OCDF based on a 10 gram aliquot of human adipose tissue. This protocol was evaluated for method performance prior to being used in this study.[12]

Statistical Considerations

Multiple comparisons and testing for differences were done by using the F test in one way analysis of variance (ANOVA) and analysis of covariance with adjustments for demographic variables such as age, collection year, and body mass index.[13] A paired t-test was conducted to compare the means of Vietnam veterans with their matched civilian controls.[14] In all analyses, the dioxin values were transformed to a natural logarithmic scale because the dioxin values were found to have approximately log-normal distributions in this study and another study.[15]

A stepwise linear regression model was also used to determine whether dioxin levels were associated with demographic and military service characteristics.[16] Factors considered *a priori* as covariates were age, adipose tissue sample collection year, race, and body mass index. A regression model specific to Vietnam veterans included such covariates as military occupation, calendar year of tour in Vietnam, geographic region in Vietnam, time of and distance from recorded Agent Orange spray, and adipose tissue sample collection year.

Results

Table 1 presents the arithmetic and geometric means, and various percentile values for dioxin for the three study groups. One-way analysis of variance did not demonstrate differences in the mean dioxin levels among groups ($p = 0.35$). Analysis of covariance, testing the effect of Vietnam service on dioxin levels after adjusting for age, sample collection year, or body mass index did not indicate an association between service in Vietnam and dioxin levels. A paired t-test between Vietnam veterans and their matched civilian pairs did not show a difference in mean dioxin levels (95% confidence interval for the difference between two means = −1.32,1.16).

For Vietnam veterans, dioxin levels were also evaluated by four factors related to the likelihood of Agent Orange exposure (Table 2). None of the surrogate measures of Agent Orange exposure was associated with the dioxin levels in adipose tissue of Vietnam veterans. Furthermore, the mean dioxin level of seven Vietnam veterans whose specimens were taken within four years (less than one dioxin half-life estimated for humans) since their last service in Vietnam were compared to 19 non-Vietnam veterans whose tissue specimen were collected on or before 1974 (the last sample collection year for the seven Vietnam veterans), and also to their matched civilian pairs. The geometric mean dioxin levels (± standard deviation) for the Vietnam group ($n = 7$), non-Vietnam veteran group ($n = 19$), and civilian controls ($n = 14$) were at the levels of 16.6 (±1.6), 15.5 (±1.5), and 18.4 (±1.6) parts per trillion (ppt), respectively. There was no difference among the means ($p = 0.56$). The 95% CI for a mean dioxin difference between Vietnam veterans and civilian controls were −1.59 and 1.31. Stepwise linear regression analysis for 36 Vietnam veterans indicated that Vietnam service characteristics could account for only 14 percent of the variation in dioxin levels ($p = 0.3$), whereas collection year alone could account for 21 percent of variance ($p = 0.005$). Five other 2,3,7,8-substituted dioxins and 10 other dibenzofurans were measured and their mean levels were calculated from specimens with levels above the detection limit (Table 3). There were no group differences in the mean level of any of the dioxin congeners. The differences in TCDD levels in the three groups were also evaluated while adjusting for levels of other 2,3,7,8-substituted dioxin congeners not found in Agent Orange by a stepwise multiple regression technique. TCDD levels were taken as the dependent variable and Vietnam service status and other dioxin congener levels as independent variables. There was a significant association between the TCDD levels and the levels of PCDD congeners ($R^2 = 0.54$, $p = 0.0001$), but not with the Vietnam service status ($R^2 = 0.0025$, $p = 0.3$).

The levels of dioxins increased with an increase in the number of chlorine except for 1,2,3,7,8,9-HxCDD. Levels of dibenzofurans were always lower than their dioxin counterparts. In each study group, the levels of dioxin tended to be inversely related to the specimen collection year, i.e. the earlier the collection year, the higher the dioxin levels ($p = 0.0001$, $n = 195$).

Discussion

In this study, military service in Vietnam was not associated with elevated dioxin levels in adipose tissue with or without adjustment for demographic variables. In addition, no Vietnam service characteristics measured singularly or in combination was a good predictor of dioxin levels in adipose tissue. There were no consistent trends in the dioxin levels ac-

cording to the surrogate measures of Agent Orange exposure. The mean levels of dioxin did rise slightly with combat MOSC and having been within three days/two km of sprayed areas. But the other two surrogates, branch of service and service location in Vietnam, were not associated with the dioxin levels. The small magnitude of the mean difference and the variation within each group suggest that the small difference in mean values could have been easily due to the sampling and measurement variation.

Analyses of adipose tissue from the general population of industrialized countries have indicated the presence of a number of 2,3,7,8-substituted dioxins and dibenzofurans at ppt level.[17-21] These dioxins and dibenzofurans could have originated from a number of sources: incineration of municipal waste and wood products; manufacturing, use and disposal of pesticides, herbicides and wood preservatives; and PCBs from electric transformers and capacitors. Because 2,3,7,8-TCDD was the only congener found in Agent Orange as a contaminant[1,7] knowing the levels of other dioxins and dibenzofurans would help determine whether TCDD levels in adipose tissue of Vietnam veterans were the result of Agent Orange exposure in Vietnam or exposure to other sources. For example, if most dioxins and dibenzofurans as well as 2,3,7,8-TCDD levels were found to be elevated among Vietnam veterans, contribution from sources other than Agent Orange should not be ruled out. However, if only the 2,3,7,8-TCDD level remained elevated and other PCDD levels were comparable to the comparison groups, Agent Orange would be considered as the contributor. There were no group differences in the mean levels of any PCDD congeners. The lack of group differences suggested that sources other than Agent Orange may have contributed to the Vietnam veterans' levels of 2,3,7,8-TCDD. In a study by Kahn, *et al*,[7] of 10 Vietnam veterans with heavy potential for exposure to Agent Orange (e.g. Ranch Hand personnel, Army Chemical Corps specialists), the levels of 12 other 2,3,7,8-substituted dioxins and dibenzofurans were similar to the levels found among 10 Vietnam veteran controls and seven non-Vietnam veteran controls. Only 2,3,7,8-TCDD levels were elevated approximately 10-fold among Vietnam veterans with a heavy exposure potential.

This study may have failed to detect a small difference in mean dioxin levels among groups because of the relatively small sample size. The study had an adequate statistical power (90 percent) to detect a mean difference of 5 ppt or more between groups. Elimination of dioxin from the body after Vietnam service is an unlikely explanation because dioxin levels of seven Vietnam veterans whose specimens were taken within four years from their return from Vietnam (which was considerably less than the estimated half-life of dioxin in humans) were not significantly different from their appropriate comparison groups.

Although the NHATS sampling scheme was designed to collect a representative sample of the SMSA in terms of age, sex and race, subjects selected for the study may not have represented their respective groups for several reasons. First, over 90 percent of the NHATS sample were collected from deceased persons whose death in most instances were due to traumatic injury. Second, tissue samples for this study were selected from the archived NHATS specimens rather than original NHATS samples. Third, 6 percent of the men who were eligible for the study had to be excluded because of missing personal identifiers. Despite these problems, demographic and military characteristics of the Vietnam veterans selected for the study did not differ substantially from the overall Vietnam veteran population. They were predominantly white (75 percent), draft eligible during the Vietnam war (age 18 to 25), enlisted men (89 percent), who served in the Army and Marine Corps (72 percent) with military occupational specialties related to combat support roles (67 percent). None of the Vietnam veterans in the study had a record of routinely handling or spraying Agent Orange.

The mean background levels of dioxin reported here were generally higher than the values reported by others.[6-9] It is unlikely that this difference is due solely to an interlaboratory variation. Our laboratory (Midwest Research Institute) participated in an interlaboratory validation study for dioxin measurement and produced a satisfactory result. Furthermore, external quality control audit samples prepared by the Battelle Columbus Division were incorporated as blind samples into the various batches and analyzed for dioxin and dibenzofuran congeners. The analytical results were found to be acceptable. We believe that the difference in sampling years between this study and several other studies could account for the higher values reported in our study. We found that the dioxin levels in adipose tis-

sue were significantly associated with the sample collection year ($p = 0.0001$), the earlier the collection year, the higher the levels of dioxin irrespective of veteran status. In fact, this general trend was observed for other dioxins. The median sample collection year in our study was 1978, whereas in other studies the specimens were mostly collected in mid 1980s or later. The observed dioxin decline from 1971 to 1982 is consistent with the general trend for chlorinated hydrocarbon chemical compounds in human adipose tissue. The US EPA's National Human Adipose Tissue Survey Program indicates that the median levels of BHC, HCB, and PCB had been steadily decreasing over [illegible] between 1970 and 1983.[11] In Sweden the levels of dioxin and dibenzofurans in human milk decreased significantly from 1972 to 1985.[22] The Swedish authors attributed the decline to the reduction in use of certain organochlorine compounds such as PCBs, PCP and 2,4,5-T. A study involving a large sample of specimens representative of the US population will be needed to confirm this observation.

We concluded that the results of our study did not support the hypothesis that most US troops were heavily exposed to dioxin in Vietnam. Furthermore, none of the surrogate measures of Agent Orange exposure based on military service characteristics was associated with the dioxin levels in adipose tissue of Vietnam veterans. These results are consistent with those of CDC[9] and not inconsistent with Kahn, *et al*,[7] and Schecter, *et al.*[8] ☐

Kellogg Grant to Strengthen Community Health Services

A grant of $1.2 million has been awarded to the Colleges of Nursing and Medicine at the University of Illinois at Chicago (UIC) by the W. K. Kellogg Foundation to strengthen community-based health service. Emphasizing leadership training for project directors, community members and health care professionals, the project will bring together community residents and health care professionals to create partnerships in advancing leadership in community-based primary health care.

Both classroom instruction and practical hands-on experience at community-based primary health care sites will be offered. UIC faculty and community leaders will serve as mentors for program participants.

For more information, contact Susan Poslusny, Office of Leadership for Primary Health Care in Urban Communities, College of Nursing (m/c 802), the University of Illinois at Chicago, 845 S. Damen, Chicago, IL 60612; (312) 413-0068.

The UCLA Population Studies of CORD: X. A Cohort Study of Changes in Respiratory Function Associated with Chronic Exposure to SO_x, NO_x, and Hydrocarbons

Roger Detels, MD, MS, Donald P. Tashkin, MD, James W. Sayre, DrPH, Stanley N. Rokaw, MD, Frank J. Massey, Jr., PhD, Anne H. Coulson, and David H. Wegman, MD

ABSTRACT

Two never-smoking cohorts in Southern California, one in Lancaster (N = 2340) exposed only to moderate levels of oxidants and the other in Long Beach (N = 1326) exposed to high levels of SO_x, NO_2, hydrocarbons and particulates completed spirometry and the single-breath nitrogen test five to six years apart. Forty-seven percent and 45 percent of the participants were retested. Mean results at baseline for those tested and not retested were similar. Loss to follow-up was primarily due to moving (39 percent and 47 percent). Every difference of consequence indicated greater deterioration in lung function in Long Beach. The level of significance of the difference was greatest, even in the youngest age groups, for $\Delta N_{2_{750-1250}}$, suggesting that the earliest site of impairment may occur in the small airways. Greater deterioration in spirometric parameters was observed in every age group in Long Beach females above seven years of age at baseline and in Long Beach males above 15 years of age, suggesting that chronic exposure to the pollutant mix occurring in Long Beach ultimately adversely affects the large airways as well as small airways. (*Am J Public Health* 1991;81:350–359)

Introduction

The relationship of temporary high levels of SO_x and particulates to health has been well documented by episodes such as those reported in the Meuse Valley, Donora, and London. A higher prevalence of symptoms of chronic obstructive respiratory disease and/or impaired lung function has been reported in cross-sectional studies in areas exposed to high levels of SO_x, NO_x, and/or particulates,[1-4] while in other studies a relationship has not been observed.[5] A number of cohort studies have also been completed, especially in adults.[6-14] The major problems encountered in cohort studies have been maintaining continuous measurement of pollutant levels and controlling for confounding factors which may change. These studies have depended primarily on the use of spirometry for measurement of lung function because of the difficulties associated with doing population studies using possibly more sensitive tests such as the single-breath nitrogen test. There is considerable evidence from experimental studies of both animals and humans that SO_2 and particulate sulfates may be responsible for bronchoconstriction,[15-24] possibly mediated through histamine release and subsequent action on bronchial smooth muscle.[25] A number of these studies have shown such effects at concentrations that occur in ambient air in some urban areas in the United States.

Previously, we reported a greater rate of deterioration in spirometric indices of the single-breath nitrogen test in residents chronically exposed to high levels of oxidants, oxides of nitrogen, sulfate, and particulates compared to an area exposed to low levels of these pollutants.[26]

In this paper we compare changes over a five- to six-year period in spirometric tests and the single-breath nitrogen test in never-smoking residents of an area chronically exposed to high levels of SO_2, sulfates, NO_x, and hydrocarbons but low levels of oxidants with changes to those in residents of another area exposed to low levels of these pollutants to which comparisons to the oxidant-polluted community were made in the previous paper.

Methods

Establishment of Cohorts

Study areas were selected in Lancaster (located 75 miles north of downtown Los Angeles) which historically has been chronically exposed to moderate levels of photochemical oxidants and very low levels of other pollutants and in Long

TABLE 1—Demographic Characteristics of Study Census Tracts in Lancaster and Long Beach*

Characteristics	Lancaster	Long Beach
Total residents, all ages	7,069	4,992
White (non-Spanish-surnamed) (%)	6,430 (91.0)	4,939 (98.9)
Spanish-surnamed (%)	434 (6.1)	0 (0.0)
Black (%)	91 (1.3)	3 (0.1)
Other (%)	114 (1.6)	50 (1.0)
Total 7+ years of age	6,121	4,691
Median income	$11,631	$11,474
Number of housing units	2,238	2,197
Proportion of homeowners (%)	63	64
Median home value	$18,600	$23,400

*According to the 1970 census.

Beach (located approximately 30 miles southwest of downtown Los Angeles) which has been chronically exposed to high levels of sulfur dioxide, sulfates, oxides of nitrogen, and probably hydrocarbons. Using 1970 census information, study areas were selected that were demographically similar, each of which contained an established air quality monitoring station. A comparison of the demographic characteristics of the two study areas according to the 1970 census is shown in Table 1. Although the Long Beach study area included a lower proportion of non-Whites, all comparisons in this paper are restricted to White, non-Spanish-surnamed residents who never smoked in order to reduce non-comparability between the cohorts. Participants were considered "never smokers" if they had never smoked more than one cigarette per day. Participants who reported smoking at either the baseline or follow-up examination were excluded from the analysis.

Cross-sectional studies conducted in the Lancaster study area in 1973–74 and in the Long Beach study area in 1974–75 demonstrated poorer lung-function in Long Beach.[27] Concurrent testing was not possible due to funding limitations. Pollutant levels in Long Beach, however, remained similar over this period of time. Details of the recruitment of the study areas have been reported previously.[26–30] Briefly, all the heads of households were identified through reverse telephone directories and voter registration files. Before explanatory letters were sent out, descriptive information regarding the program was presented in the local media. Following the mailing of individualized letters, a neighborhood representative set up an appointment to complete a roster of all household members seven years of age and older and to arrange appointments for lung function testing at the Mobile Lung Function Laboratory, which was located within walking distance.

At the Mobile Laboratory, an interview schedule modified from the National Heart, Lung and Blood Institute Questionnaire was administered; this contained questions concerning respiratory symptoms, and history of respiratory disease, occupation, smoking, and residence. Height and weight were recorded, and the following pulmonary function tests were done: body plethysmography; single-breath nitrogen washout curve, including calculation of $\Delta N_{2_{750-1250}}$* and closing volume; and electronic spirometry measurement with permanent recording of the entire maximal expiratory flow volume relationship on computer tape. The test equipment used was the same for all the testing except for the recorder for the spirometer. The new recorder, however, was thoroughly calibrated to the old recorder before being put into use. Details of the instrumentation used and the procedures followed are contained in previous papers.[28,29] Results of body plethysmographic tests were inconsistent at baseline; thus, changes in these tests could not be determined with confidence. Details of the procedures for administering the single-breath nitrogen test and spirometry are given in Appendix A.

Retesting of the Cohorts

Approximately five years in Lancaster and six years in Long Beach after the baseline studies, retesting in each of the study areas was completed (1978–79 in Lancaster and 1980–81 in Long Beach). Results, however, have all been expressed as annualized rates of change. In the interval between baseline testing and retesting, addresses had been updated through periodic mailings to all participants. Study participants were recontacted and invited to be retested in the same month in which they had originally been tested. Individuals who had moved but remained within a reasonable distance were also encouraged to undergo retesting at the Mobile Laboratory. Intensive efforts were made to persuade all participants to be retested, including call back within one day of individuals who did not keep their appointments at the Mobile Lung Function Laboratory. The procedures for retesting were identical to those used at baseline; the tests were administered in the same sequence and in the same manner.

Individuals who had moved out of the original study area were requested to undergo retesting at the Mobile Laboratory if they visited the Southern California area. Participants who had moved outside of the study area to a known address and who could not be retested were asked to complete a brief questionnaire on respiratory symptoms, smoking, and reasons for moving from the study area, including a final question that asked if the reason for moving was related to respiratory problems.

Validation and Quality Control

Procedures were implemented to calibrate and maintain the reliability of the lung function tests and to assess the effects of concurrent levels of air pollutants. These have been described in detail previously.[29,31] Briefly, they included the following:

Calibration: At the beginning of the testing period in each area the results of lung function testing in the Mobile Laboratory were compared with results obtained from the UCLA (University of California at Los Angeles) Pulmonary Function Laboratory on 10 to 20 participants who were tested on the same day in both laboratories in a randomized sequence. At the beginning of each day's testing in the field and at regular intervals during the testing, the test equipment was recalibrated using standard procedures. In addition, calibration values were recorded on computer tape and evaluated at the end of each test day at UCLA. The Mobile Laboratory was immediately notified of any signs of error or "drift" so that if needed, the instruments could be adjusted before testing commenced the next day. Individuals tested the previous day were

*24 hour standard
**median value

asked to undergo retesting; results for those not retested were deleted.

Reliability and Validity: The reliability of the test procedures was evaluated by requesting every tenth individual completing lung function testing to undergo repeat lung function testing within 20 minutes and comparing the results. In addition, a 3 percent probability sample of participants was asked to undergo additional testing at the UCLA Pulmonary Function Laboratory, usually within two to three months of field testing. The results of the tests in the two laboratories were compared.[26,29]

Effect of Concurrent Pollutant Levels: The possible effect of levels of air pollutants on the day of testing was evaluated by comparing lung function test results in 40 participants in Lancaster and 35 participants in Long Beach tested three times at four-month intervals in each study area. In addition, O/P (observed/predicted — adjusted for age, height, and weight) forced expiratory volume in one second (FEV_1) for all of the adult participants retested was analyzed relative to the level of pollutants recorded for the day on which their test was performed.[30]

Levels of Air Pollutants

Monitoring stations of the Southern California Air Quality Monitoring District located in the two study areas continuously recorded levels of total oxidants, nitric oxide, nitrogen dioxide, total oxides of nitrogen, total hydrocarbons (Lancaster only), and sulfur dioxide.[31] In addition, 24-hour totals for total suspended particulates (TSP) and for sulfates (at six-day intervals) were monitored. The maximum hourly level for oxidants, SO_2 and NO_x, and the 24-hour total for TSP and SO_4, as recorded at the respective monitoring station on the day of testing, were attached to each individual's computer record. All measurements met both the California and federal Environmental Protection Agency guidelines for acceptability of testing procedures for these pollutants.

Results

Levels of Pollutants during the Study Period

The annual means of the daily peak hourly values for SO_2, oxidants, NO_2, and of the 24-hour total value for SO_4 and TSP over the 10-year period are shown in Table 2. The table also gives the average number of days per year on which SO_2, oxidants, NO_2, and TSP exceeded the California ambient air quality standard. Days exceeding these levels were not recorded for all years between 1972 and 1981.[31,32] The years contributing to the determination of the mean number of days are given separately for each pollutant. In terms of both days above California ambient air quality standards and means of the daily peak hourly levels, the largest differences in recorded pollutants were in levels of NO_2. Levels of all indicated pollutants except oxidants, however, were higher in Long Beach. On the other hand, there was a five-fold greater number of days on which oxidants exceeded 0.08 or 0.10 ppm in Lancaster, but less than a two-fold difference in the annual means of the daily peak hourly levels between the two communities. Although the level of oxidants in Lancaster was lower than in most other areas of the Southern California air basin, it was nonetheless higher than in most urban areas in the United States. Unfortunately, levels of hydrocarbons were not measured at the Long Beach monitoring station, but the location of the study area directly downwind from the major oil refining area in Los Angeles and the results of interpolation from adjacent monitoring stations suggest that levels of hydrocarbons were also very high in the Long Beach study area.

Response Rates

Response rates for the two cohorts are given in Table 3. The proportion remaining in the study area who completed all of the lung function tests was reasonably high in both areas (75 percent and 77 percent). An additional 6 percent and 9 percent, respectively, completed only the questionnaire. One percent of participants in both areas were known to have died. The major problem in follow-up was the high proportion of individuals who moved out of the study area: 39 percent (910/2340) in Lancaster and 47 percent (629/1326) in Long Beach. In Lancaster, only 12 percent (270/2340) and in Long Beach only 7 percent (94/1326) of participants refused to be retested. The overall retest rate, excluding deaths, for persons completing *all* lung function tests was 47 percent for Lancaster and 45 percent for Long Beach.

The proportions retested, stratified by age, sex, and place of residence, are given in Table 4. The proportion retested tended to be lower for individuals who were 11–24 years of age at baseline testing, a finding not unexpected in this highly mobile age group leaving home for college and jobs over the five- to six-year interval between baseline testing and retesting.

Because the overall retest rate was not as high as we would have liked, a comparison was made in Table 5 of the lung function test results at baseline among those who completed retesting and those who did not. The high mean observed/predicted values at baseline for those retested reflects the fact that they repre-

sent volunteers who survived for five to six years and were still willing to be retested. Thus, the mean of their observed/predicted test performance at baseline does not reflect the mean for the entire group tested at baseline.

Validity of Results

The mean test/retest results for those 10 percent immediately retested were within 5 percent for the major spirometric indices. Regression analysis of the level of air pollutant on day of testing and the mean test value for FEV_1 for that day for all participants revealed no statistically significant correlations. Of the 24 comparisons made of results of FVC, FEV_1, FEF_{25-75}, FEF_{50-75}, $\Delta N_{2_{750-1250}}$, and closing volume in the two groups of participants tested at different seasons of the year, only one, $\Delta N_{2_{750-1250}}$, was significant at the $p < 0.04$ level; equivalent to chance for this number of comparisons. Mean test results in the cohort retested in three different seasons were not significantly different.

An estimate of the possible impact of errors resulting from the testing procedures in the mobile lung function laboratory was calculated by comparing the results of FEV_1 in the 3 percent probability sample of adults tested in both the mobile and the UCLA lung function laboratories. (Levels of pollution at UCLA fall between those in Lancaster and Long Beach except that the levels of oxidants are higher at UCLA than in either study area.) The mean interval between testing in the mobile and UCLA laboratories was several months.

The difference between FEV_1 values at the Mobile Laboratory were greater at T_2 (retesting) than at T_1 (baseline) in both communities although mobile laboratory values were lower at both examinations. If the UCLA laboratory results represented the true values, then the greater inter-laboratory differences at T_2 than at T_1 suggest that the annual decline in FEV_1 as measured in the field laboratory might have been exaggerated. Furthermore, comparison between the two communities of the inter-laboratory differences at T_2 versus T_1 suggests that this potential exaggeration of the annual decrement in FEV_1 was slightly greater in Long Beach (−13 ml/year, SE ± 7 ml/year) than in Lancaster (−2 ml/year, SE ± 7 ml/year). These decrements were not statistically different. Further, these differences observed in the 3 percent probability sample may not have existed in the entire group tested. The response rate for retesting of the 3 percent probability sample at T_2 was less than 50 percent.

Changes in Lung Function Tests

The means of the individual changes in tests are shown in Table 6A, for males and females 25–59 years of age, and stratified into five age groups for males (Table 6B) and females (Table 6C) 7–24 years of age at baseline. Non-adults were stratified to separate the growth phase of childhood from the declining trend in lung function which begins in late adolescence, as we have reported previously.[33] The levels of significance of differences between results in the two areas are shown in Table 7 for those age-and-sex-specific groups in which the probability was less than .05.

Changes for $\Delta N_{2_{750-1250}}$ and the spirometric indices except V_{75} were significantly worse in Long Beach participants 25–59 years. The level of significance for the difference in baseline and follow-up test results was highest for the single-breath nitrogen test. The levels of signifi-

cance of the differences were higher for most tests for adult women than for men except for the $FEF_{25-75\%}$.

Among non-adults, a significantly less favorable change in the results of the single-breath nitrogen test was observed in the youngest age group (7–10 years) for both males and females in Long Beach. A less favorable change in the results of the single-breath nitrogen test was observed in every age group under 25 years in Long Beach, but was not statistically significant in the 11–14 and 19–24 year groups among males and in the 15–18 year old group in females.

Among non-adult females the changes in spirometry were worse among Long Beach participants in every age group except for the $\dot{V}_{75}$ in the 7–10 year group and reached statistical significance for at least one spirometric test in every age stratum (Table 6C). Among males under 15 years, however, spirometry was not consistently worse in Long Beach participants. Above 15 years spirometry was consistently worse in Long Beach male participants, but did not reach statistical significance in the 15–18 year group. Above 19 years the results were significantly worse in Long Beach participants for all the spirometric indices except $\dot{V}_{75}$.

In every instance in which a statistically significant difference was observed the rate of change was worse among residents of the more polluted area, Long Beach. These included tests believed to reflect both small and large airways function. A significantly greater rate of deterioration was observed at an earlier age among females than among males.

Discussion

Although cohort studies provide the only absolute measures of risk in human populations, a number of problems arise in successfully completing them. Probably the most important is to achieve follow-up of a high proportion of participants. The proportion of all living participants completely retested in this study was low (47 percent and 45 percent in Lancaster and Long Beach, respectively). The major reason for not being retested, however, was not refusal, but migration out of the study area (39 percent and 47 percent, respectively.) The proportion completely retested of those remaining in the study areas was relatively high (75 percent and 77 percent). In the interval between baseline and retesting only a small percentage of participants moved

because of respiratory problems (2.1 percent in Long Beach and 0.5 percent in Lancaster).

A major way of assessing the impact of a lower-than-desired response rate is to determine the differences in the baseline test results between participants who were retested and those who were not. The difference in the mean test indices at baseline were not significantly different in those who were not retested than in those who subsequently completed lung function retesting, suggesting that those who were not retested were substantially similar in respiratory function to those who were.

A particular problem for cohort studies of the relationship of air pollution to changes in lung function test results is the possible impact of air pollution levels on the day of testing.[8] For that reason, analysis was carried out comparing the results of lung function testing with levels of each of the major pollutants on the day of testing. No significant correlations with test results were seen and no consistent pattern emerged for the major pollutants occurring at higher concentrations in Long Beach, suggesting that the range of levels of these pollutants prevailing during the testing periods had relatively little impact on the results of the lung function testing in this study.

The tests used in this study can be affected by a number of confounding factors including instrument characteristics, subject effort, and technician performance.[29] Thus, there is continual concern with the accuracy and reliability of the equipment and testing procedures, particularly in a mobile laboratory in which movement of the equipment from site to site can precipitate instrument drift. For that reason, the test-retest difference in FEV_1 observed in the five to six year interval in the Mobile Lung Function Laboratory was compared with results obtained on a 3 percent subsample of participants tested on both occasions at the UCLA Reference Laboratory. This comparison revealed only a small difference between the two laboratories in favor of showing a slightly greater deficit in FEV_1 in Long Beach if, in fact, the difference in deficit was also present in the entire group tested.

For the lung function tests, the mean of the absolute change in individual test results was used rather than differences in predicted values. Thus, differences between communities in age and height could have biased the results. The mean height was, however, similar in the two

areas. The mean ages of the two populations were similar although the females in Long Beach were on average three years older than females in Lancaster, whereas the males in Long Beach were on average one year younger than in Lancaster. A prior study of this population suggested that the rate of decline in FEV_1 remained fairly constant over the age range 25–59 years.[33]

Recent reports have suggested that young individuals living in homes supplied with gas, especially for cooking, may have more respiratory problems than persons in homes that are supplied with electricity.[34–38] The percentage of homes that used gas for heating, however, was exactly the same in both communities (94 percent).

Many people in Southern California commute long distances to workplaces in which they may experience air pollution patterns different from those at their place of residence. Individuals in Long Beach commuted to areas of lower levels of the major pollutants (except for oxidants), whereas most residents of Lancaster who commuted did so to areas of higher levels of pollution.[28] This pattern would tend to minimize the actual difference in pollutant exposures for participants in the two study areas and, thus, would reduce the likelihood of observing a pollution effect on lung function test results.

A number of other factors that could have biased the results have been dealt with by restricting the population analyzed in this paper. Differences in racial distribution were reduced by including only White non-Spanish-surnamed participants in the analyses and by excluding individuals who reported a history of changing residence or occupation because of a respiratory problem at baseline. The number of individuals who had worked in an occupation that might be associated with respiratory injury was too high to permit excluding them from analysis. Their occupations were not concentrated in any one or two types of exposure and the duration of their employment in any type was generally less than five years. The proportion with such a history, however, was higher in Lancaster than in Long Beach and, thus, including them in the analysis probably reduced the likelihood of observing less favorable changes in Long Beach.

The average annual change in FEV_1 among these never-smoking adults was higher than has been reported in most previous population studies.[6–8,39–41] The levels observed in our study are comparable with some of the more recent reports of changes in lung function over time in occupational groups.[42–44] Although we looked intensively for methodologic problems that may have caused these large rates of decline in adults, we were unable to identify any consistent factors that would account for the magnitude of decline observed in FEV_1. One possibility is that these large average annual declines in FEV_1 may reflect the accumulated respiratory effects of chronic exposure to air pollution. Supporting this hypothesis is the previous observation that the annual rate of decline in FEV_1 between 25 and 59 years of age in these populations increased only very slightly with age[33] in contrast to the significant increase in the annual rate of decline with aging reported in other publications.[45,46] Because of local migration patterns, fewer of our older participants and more of our younger participants were raised in the Los Angeles area. This, and the consistently poorer (more positive) changes in $\Delta N_{2750-1250}$, even in the youngest participants in Long Beach, suggest that the younger members of our cohorts raised in Los Angeles may experience greater drops in their lung function test parameters when they reach later life than the drop currently observed in the older members of our cohorts who were raised in less polluted areas. If in fact this hypothesis is true, it is cause for concern.

The test demonstrating differences most frequently and with the highest levels of significance was the $\Delta N_{2_{750-1250}}$. Furthermore, in the youngest age groups this test often demonstrated the only significantly worse deterioration, suggesting that physiologic changes may be occurring in children that are not as readily identified by the presumably less sensitive spirometric tests until adulthood. Since the $\Delta N_{2_{750-1250}}$ is thought to reflect function primarily in the small airways, the results of this cohort study suggest that this may be the site of earliest injury due to exposure to the type of air pollutants found in the Long Beach area. Buist and colleagues[47] and McCarthy, *et al*,[48] have demonstrated that the single-breath nitrogen test is more sensitive than spirometry in detecting early functional abnormality involving the small airways. In cross-sectional studies we were not able to observe differences between communities in this parameter.[27,28,30] We had previously observed, however, that the $\Delta N_{2_{750-1250}}$ is subject to considerable variability which may account for the difficulty in identifying significant differences in cross-sectional studies.[49] Inter-subject variability may be a greater problem in cross-sectional studies than intra-subject variability in cohort studies in which differences in two measurements from the same individual are being considered.

Among adults who never smoked, rate of decline in all of the tests noted in Table 7 was significantly worse in residents of Long Beach except for the $\dot{V}_{75}$ in which a directionally similar difference did not attain statistical significance.

Although the large differences in the results of $\Delta N_{2_{750-1250}}$ in children in even the youngest age groups suggest that the small airways are the earliest site of pathology resulting from chronic exposure to the mix of air pollutants occurring in Long Beach, the greater deterioration in the spirometric indices indicates that by the time residents of the area reach adulthood, the adverse changes in the small airways have progressed and/or the large airways have become affected as well. It remains to be determined if the adverse changes in the lungs resulting from chronic exposure to this mix of pollutants causes sufficient respiratory impairment over a lifetime to reduce their ability to function satisfactorily or only reduces their considerable reserve capacity without causing clinically significant functional impairment.

Ware, *et al*, have studied the respiratory symptom and lung function effects of chronic exposure to TSP, SO_2, and TSO_4 at two different examinations one year apart in children 6–10 years of age in six cities in the United States and have found no relationship between respiratory parameters and levels of these pollutants.[50] While it is tempting to compare the results of that study to the present study there are several problems with doing so. First, the measures of air pollutants were different. Whereas Ware, *et al*, used the mean of the 24-hour values, we used the means of the daily peak hourly values for SO_2, although for TSP and TSO_4 we used the 24-hour totals. Of greater importance is the fact that we looked at the mean annual change in lung function values within each individual over a five to six year interval whereas Ware, *et al*, looked at the correlations of the pollutant values with FEV_1 and FVC at two time periods only one year apart. Thus, their study design was essentially two consecutive cross-sectional correlations to mean lung function values for groups of children in each area whereas we looked at the mean of change within each individual over a five-year period. Nonetheless, there are some similarities between the studies. Neither found consistent correlations between respiratory symptoms and levels of air pollutants. Further, we did not observe a significant correlation between change in lung function and pollutant level in males 7–10 years of age. The correlation we observed in both males and females 7–10 years was in the single-breath nitrogen test, a possibly more sensitive measure of early decrement in lung function. It will be interesting to observe whether Ware, *et al*, find correlations between pollutant levels and lung function with additional follow-up of the children in these six cities. We did not consistently observe significant differences in FEV_1 and FVC in boys until 15–18 years. We did, however, observe consistent difference in earlier age groups using the single-breath nitrogen test.

We previously observed a greater deficit in several lung function test parameters between Lancaster and an area subject to very high levels of oxidants, Glendora.[26,30] The greatest difference in pollutant exposures between Long Beach and Glendora was in the levels of oxidants (much higher in Glendora), nitrogen dioxide (higher in Long Beach), and SO_2 (higher in Long Beach). Mean levels of SO_4 were similar in these two communities and higher than in Lancaster which had primarily oxidant exposure, which, although high, was half that in Glendora. In the Long Beach comparison, the measures incorporating the large airways (FEV_1, FVC) were consistently significantly different in adults whereas only the FEV_1 in adult females in the Glendora comparison were significant. On the other hand, a significant difference in $\dot{V}_{75}$ was observed only for Glendora. The deterioration in the single-breath nitrogen test in Glendora was significantly worse in every age-sex group under 25 years compared whereas they were significantly worse only in males 7–10 years and 15–18 years and in females 7–14 and 19–24 years in Long Beach. Significant differences in most of the spirometric indices in these younger age groups were not consistently identified in either polluted community compared to Lancaster. It is possible that the type of pollutants that were present in greatest concentrations in Long Beach (NO_2, hydrocarbons, and SO_2) were more likely to cause damage in the large airways whereas oxidants were more likely to cause damage in the smaller airways as reflected by the greater magnitude of differences for the $\Delta N_{2_{750-1250}}$ and $\dot{V}_{75}$ in Glendora. Further, exposure to oxidant pollutants may cause measurable damage earlier (according to the single-breath nitrogen test) than SO_2 and NO_2. These interpretations are consistent with results of controlled exposure studies in experimental animals which demonstrate that characteristic ozone-induced lesions occur in the lung periphery (centiacinar region)[51,52] while chronic exposure to SO_2 produces clinical, physiologic, and histologic changes of chronic bronchitis with greater involvement of proximal than distal airways.[53]

Given the nature of epidemiological studies which must deal with populations as they actually exist in the community rather than with laboratory animals which can be kept under experimental conditions, these inferences should be investigated further. It appears, however, that chronic exposure to either mix of pollutants results in less rapid growth of lung function in children and a greater rate of deterioration in adulthood.

These observations have serious implications for safeguarding the health of the public and controlling levels of pollutants in urban areas in the United States. These studies need to be verified by others, but the implications for health should not be ignored by legislators and government administrators. Given the difficulties of carrying out epidemiologic studies of cohorts of individuals over long periods of time the probability of being able to observe statistically significant differences is smaller than for similarly designed studies done under laboratory conditions. For this reason, the burden of proof should now be to prove that high levels of these pollutants do not affect lung function and, therefore, until that is demonstrated efforts should be increased to improve the quality of air in the urban areas of the United States. ☐

APPENDIX A

Single-breath Nitrogen Test

Ventilation distribution was determined using an Ohio-Series 700 nitrogen analyzer, Electro-Medical (Ohio Medical Products, Houston) model 780 spirometer, electronics module, samplehead assembly, remote vacuum pump assembly, and Hewlett-Packard X-Y recorder (Hewlett-Packard, San Diego) with time base.

Subjects performed these tests in the standing position with a nose clamp and flanged rubber mouthpiece in place. After a few normal tidal breaths and stabilization of the system, the subject was asked to exhale completely and to hold his breath briefly at the residual volume position. The valve was switched to the reservoir containing 100 percent oxygen and the expiratory port simultaneously opened to the (electronic) spirometer. The subject was asked to inhale fully and deeply, within less than 4 seconds, to total lung capacity, then to exhale slowly and completely at a constant flow rate maintained between 0.5 and 0.8l/s according to an X-Y tracing which was visible to him. Residual volume was reached over no longer than 10 s. The expired volume and expired nitrogen concentrations were simultaneously recorded on the horizontal and vertical axes of the X-Y recorder. A minimum of three trials was completed for each resident.

Each tracing was read by only one individual, the Chief Technologist, who assigned values for the percentage of nitrogen (percent N_2) in the expired air at 750 and 1,250 ml of expirate and identified both the point at which the inflection between phase III and Phase IV occurred and the point at which total volume was exhaled (residual volume).

A Measles Outbreak at a College with a Prematriculation Immunization Requirement

Bradley S. Hersh, MD, MPH, Lauri E. Markowitz, MD, Richard E. Hoffman, MD, MPH, Daniel R. Hoff, PA, Mary J. Doran, Jessica C. Fleishman, Stephen R. Preblud, MD, and Walter A. Orenstein, MD

ABSTRACT

Background. In early 1988 an outbreak of 84 measles cases occurred at a college in Colorado in which over 98 percent of students had documentation of adequate measles immunity (physician diagnosed measles, receipt of live measles vaccine on or after the first birthday, or serologic evidence of immunity) due to an immunization requirement in effect since 1986.

Methods. To examine potential risk factors for measles vaccine failure, we conducted a retrospective cohort study among students living in campus dormitories using student health service vaccination records.

Results. Overall, 70 (83 percent) cases had been vaccinated at ≥12 months of age. Students living in campus dormitories were at increased risk for measles compared to students living off-campus (RR = 3.0, 95% CI = 2.0, 4.7). Students vaccinated at 12–14 months of age were at increased risk compared to those vaccinated at ≥15 months (RR = 3.1, 95% CI = 1.7, 5.7). Time since vaccination was not a risk factor for vaccine failure. Measles vaccine effectiveness was calculated to be 94% (95% CI = 86, 98) for vaccination at ≥15 months.

Conclusions. As in secondary schools, measles outbreaks can occur among highly vaccinated college populations. Implementation of recent recommendations to require two doses of measles vaccine for college entrants should help reduce measles outbreaks in college populations. (*Am J Public Health* 1991;81:360–364)

Introduction

Since licensure of live measles vaccine in the United States in 1963, there has been a marked reduction of reported measles incidence. In 1978, the United States began an effort to eliminate indigenous measles. The elimination strategy called for achieving and maintaining high immunization levels, careful surveillance, and aggressive outbreak control. The high immunization levels were to be achieved using a single dose of measles vaccine.[1]

Although there has been a 98 to 99 percent reduction in the number of annual reported cases from the pre-vaccine era, measles outbreaks still occur. Two predominant patterns of measles transmission have been observed: outbreaks occurring in predominately unvaccinated inner-city preschool-age children, and outbreaks occurring in highly vaccinated secondary school and college populations.[2,3] While most outbreaks occur in secondary schools, cases from college campuses have accounted for between 1.5 percent and 19.8 percent of cases each year from 1980 to 1989 (Table 1).[4,5] In 1983, the record low year for reported measles cases, campus outbreaks and non-campus cases associated with these outbreaks accounted for 32.4 percent of total cases.[6]

There are several reasons why measles outbreaks may be likely to occur in colleges and universities. Some college-aged students may not have been vaccinated in the early years following licensure of measles vaccine; others may not have been appropriately vaccinated at school entry or thereafter. Data from serological surveys suggest that between 5 and 15 percent of college-aged individuals may be susceptible to measles.[7] The propensity for college students to congregate in large groups and their travel to areas where measles transmission is endemic may increase the potential for introduction and spread of measles virus on college campuses.

School immunization laws have been demonstrated to be an effective means of assuring high measles vaccination levels and preventing measles outbreaks among kindergarten through 12th grade children and adolescents.[8] The American College Health Association[9–11] and the Immunization Practices Advisory Committee of the US Public Health Service (ACIP)[12] have recommended that colleges and universities require students to present evidence of measles immunity as a condition for enrollment. In early 1988, a measles outbreak occurred at a college that had implemented such an immunization requirement. This outbreak provided an opportunity to investigate the occurrence of measles in a highly vaccinated college population and to examine potential risk factors for measles vaccine failure.

TABLE 1—Reported Measles Cases on US College Campuses, 1980–89

Year	Total US Cases	Campus Cases No.	Campus Cases %	No. of Colleges Reporting Cases
1980	13,506	200	(1.5)	36
1981	3,124	101	(3.2)	19
1982	1,714	115	(6.7)	14
1983	1,497	296	(19.8)	19
1984	2,587	67	(2.6)	17
1985	2,822	354	(12.6)	26
1986	6,282	174	(2.8)	21
1987	3,655	141	(3.9)	22
1988	3,396	267	(7.9)	20
1989	18,193	1,643	(9.0)	93

Background

Fort Lewis College is a public four-year college in Durango, Colorado. There were 3,555 students registered at the time of the outbreak. Since September 1986, the college has required students to provide proof of immunity to measles, as well as to other vaccine-preventable diseases, before enrolling. Adequate measles immunity was considered documentation of physician-diagnosed measles, receipt of live measles vaccine on or after the first birthday, or serologic evidence of immunity. Prior to this outbreak almost 99 percent of the student population were in compliance with this requirement and had documentation on file at the student health center.

Methods

Case Definition and Case Ascertainment

A case of measles was defined as an illness that met the Centers for Disease Control clinical case definition[13] (generalized maculopapular rash ≥3 days duration, fever ≥101 F, if measured, and at least one of the following: cough, coryza, or conjunctivitis). A suspected case was any rash illness with fever; a confirmed case met the clinical case definition and was either serologically confirmed or epidemiologically linked to another confirmed or clinical case of measles. A case was considered to be serologically confirmed if there was a fourfold rise in titer between acute and convalescent specimens by the complement-fixation assay.

Students were informed about the outbreak by class announcements, articles in the student newspaper, and reports on the campus radio station. They were instructed to report to the student health service at the onset of any febrile or rash illness. A disease control specialist from the Colorado Department of Health investigated every suspected case.

Outbreak Control

On January 8, 1988, after the third clinical case of measles was reported at the college, a manual review of college immunization records was conducted. A total of 40 students were found without documentation of measles immunity. All but three of these students were promptly vaccinated. The students not vaccinated had medical exemptions to vaccination and were excluded from campus for the duration of the outbreak. On January 12, 1988, the Colorado Department of Health placed the campus under public health orders. All indoor sporting events and other indoor college activities on or away from campus were restricted to participants who could show proof of measles immunity. All Fort Lewis participants in intercollegiate activities were examined prior to an event for signs and symptoms of measles prodrome. Furthermore, no spectators were allowed to attend these events. In order to prevent further measles transmission, all suspected measles cases among Fort Lewis College students were isolated in special dormitory rooms located near the student health service.

Retrospective Cohort Study

To investigate risk factors for measles vaccine failure, we conducted a retrospective cohort study among all students living in campus dormitories. Vaccination histories were obtained from student health center vaccination records. Student variables collected include: name, sex, race, class, date of birth, and housing status. Students who had received measles vaccine less than 14 days prior to rash onset were considered to be unvaccinated. We investigated the following potential risk factors for vaccine failure: number of doses of measles vaccine received, age at vaccination, and time since vaccination. Since several investigations of recent measles outbreaks have found individuals vaccinated before 1980 to be at higher risk for measles than those vaccinated in 1980 or after,[14] we also evaluated year of vaccination.

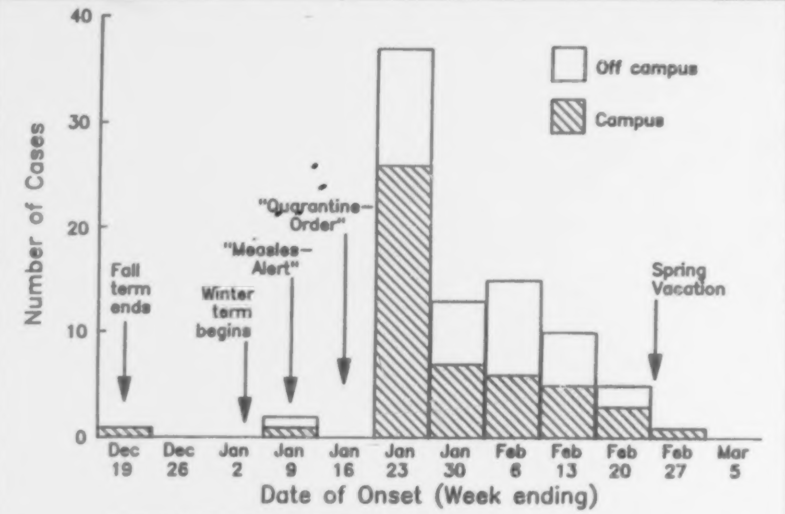
Age at vaccination was defined as the number of months between the date of birth and the most recent vaccination date on the vaccination record. Time since vaccination was calculated as the number of years between the date of most recent vaccination and the beginning of the outbreak (January 1, 1988). The age-at-vaccination analysis was limited to single dose vaccinees who were vaccinated before 1980; the time-since-vaccination and year-of-vaccination analyses were limited to single dose vaccinees who were vaccinated at 15 months of age or older. Finally, in order to verify information contained in case vaccination records, efforts were made to contact health care providers who had administered the vaccine. A physician-verified vaccination record was defined as confirmation of at least month and year of vaccination.

Differences in attack rates among groups in the retrospective cohort study were measured using the chi-square and Fisher's exact tests. Measles vaccine effectiveness and 95 percent confidence intervals were calculated using the method described by Orenstein, et al.[15]

Results

Between December 15, 1987, and March 10, 1988, a total of 84 measles cases in five generations of measles transmission occurred among Fort Lewis College students (Figure 1). All cases satisfied the clinical case definition for measles. Of the total cases, 11 (13 percent) were serologically confirmed.

The index case was an 18-year-old female freshman from South Carolina who had been vaccinated against measles at 14 months of age. The source of her infection is unknown. Measles transmission from the index case to second generation campus cases occurred at the Durango airport. Further measles transmission occurred primarily in campus dining halls, in classrooms, and at several campus social events. There was no spread of measles to other schools despite 10 inter-collegiate indoor activities or games, and only five cases were reported among non-college



Source: Colorado Department of Health

FIGURE 1—Reported Measles Cases by Week of Rash Onset, Fort Lewis College, December 1987–March 1988.

residents of Durango. Two of the non-college cases were directly linked to the index case.

Of the 84 cases, 70 (83 percent) occurred in individuals with evidence of measles vaccination at 12 months of age or older, including 20 (24 percent) vaccinated at 12 to 14 months of age. Of the 70 cases, vaccination histories (89 percent) were verified by the physician who had administered the vaccine. Five cases (6 percent) occurred in persons vaccinated before the first birthday, and 9 cases (11 percent) occurred in persons without documentation of measles vaccination. Of the cases in students without documentation of measles vaccination, vaccine was not routinely recommended for four (two born before 1957, two with a history of physician-diagnosed measles), and a fifth student had a religious exemption to vaccination.

Forty-six cases (55 percent) were freshmen, 46 (55 percent) were males, and 53 (63 percent) occurred in students living in campus dormitories. Seventy-five (89 percent) cases were White, seven (8 percent) were Native American, one case (1 percent) was Black, and one (1 percent) was Hispanic. Cases ranged in age from 17–32 years; 62 (74 percent) occurred in persons 18–20 years of age.

The overall attack rate among Fort Lewis College students was 2.4 percent. There were no differences in attack rates by race. Attack rates by housing status, sex, and class are summarized in Table 2. Students living in campus dormitories were at higher risk for measles than students living off-campus. When the analysis was limited to students living in campus dormitories, differences in attack rates by class are no longer observed.

In the retrospective cohort study among students living in campus dormitories, students without documentation of measles vaccination and those vaccinated before 12 months of age were at greater risk for measles than students vaccinated at 12 months of age or older (Table 3). No case of measles occurred in 46 students who had received two doses of measles vaccine after 12 months of age. Students vaccinated once at less than 12 months or at 12 to 14 months of age were at greater risk for measles than those vaccinated once at 15 months of age or greater. Although students vaccinated prior to 15 months of age were at increased risk for measles, these cases accounted for only 30 percent of the total cases. Students vaccinated before 1980 were not at significantly increased risk for measles compared with those vaccinated in 1980 or after. No trend for increasing attack rate with increasing time since vaccination was observed among students vaccinated once at 15 months of age or older (Figure 2).

The estimates of vaccine effectiveness among students living in campus dormitories was 80 percent (95 percent CI = 51–92 percent) for vaccination at 12 to 14 months of age and 94 percent (95 percent CI = 86–98 percent) for vaccination at 15 months or greater.

Discussion

The Fort Lewis College measles outbreak occurred in spite of virtually complete implementation of a prematriculation measles vaccination requirement. It was thus similar to outbreaks that have occurred in recent years among highly vaccinated junior and senior high school populations.[16–21] While the prematriculation requirement may have prevented a larger outbreak, it is apparent that measles outbreaks, such as the one described, can occur in highly vaccinated populations.

In this outbreak, living in campus dormitories was found to be a risk factor for acquiring measles. The relatively crowded living conditions and high contact rate among students in a college dormitory can facilitate measles virus transmission from infected to susceptible individuals.

Consistent with other investigations,[22] vaccination before the age of 15 months was found to be a risk factor for measles vaccine failure. The increased relative risk observed in persons vaccinated before 15 months of age has been attributed to the persistence of maternal antibody in infants, which interferes with live measles vaccine. Although age of vaccination was found to be a risk factor, 60 percent of cases occurred in students vaccinated at 15 months or older. As in other investigations,[17,19,21,23,24] there was no evidence in this outbreak that the risk for measles increases with time since vaccination.

We did not find evidence that vaccination prior to 1980 was a risk factor for measles in this outbreak. Other investigations, however, have found this to be a risk factor for measles vaccine failure.[14] Prior to the addition of an improved heat stabilizer to measles vaccine in 1979, individuals may have received a less effective vaccine, causing lower rates of seroconversion and an increased risk for measles. Alternatively, one may speculate that the finding of a lower risk for measles in individuals vaccinated since 1980 may be due to the possibility that some of these persons may have, in fact, been receiving a second dose of measles vaccine. Students may often find it easier to receive a second dose of measles vaccine than to obtain documentation of their initial measles vaccination.

The investigation of this outbreak found measles vaccine to be over 90 percent effective for vaccination at 15 months or greater. Other investigations have found similar results.[25] The occurrence of

*Among students living in campus dormitories.

measles outbreaks in populations with high immunization levels suggests that the estimated 5 to 10 percent vaccine failure rate may still provide enough susceptibles to allow sustained transmission of a virus as communicable as measles in some settings, such as a college dormitory.

The two national advisory bodies for immunization policy, the Committee on Infectious Diseases of the American Academy of Pediatrics (Red Book Committee) and the ACIP, have recently considered the problem of measles outbreaks in highly vaccinated populations and have recommended the institution of a routine two-dose measles vaccination schedule.[26,27] Furthermore, both committees recommend that college students have, at the time of college entry, documentation of having received two doses of measles vaccine after the first birthday. The American College Health Association has endorsed this recommendation.[28] Prematriculation immunization requirements provide a mechanism for colleges and universities to ensure that students are in compliance with this new recommendation.

Whether a second dose of measles vaccine will significantly increase population measles immunity and decrease the risk of measles outbreaks is not conclusively known. However, this investigation and several others have found lower risks for measles in persons who received two doses of vaccine.[17,19,21,23] The power of these studies to detect statistically significant differences, however, was low due to the relatively small number of multiple dose vaccinees. Experience from the military suggests that a second dose of measles vaccine should be effective in preventing outbreaks.[29]

Measles elimination has proved more difficult than previously predicted.[30] A single dose strategy, while highly effective, has not been able to totally prevent measles outbreaks. The full implementation of a routine two-dose measles vaccination schedule, however, should help reduce measles outbreaks in highly vaccinated populations. ☐

Assessment of Drug Abuser Treatment Needs in Rhode Island

William E. McAuliffe, PhD, Paul Breer, PhD, Nancy White Ahmadifar, PhD, and Cathie Spino, DSc

ABSTRACT

Background. Rhode Island's Division of Substance Abuse asked us to assess the State's drug treatment needs and make recommendations regarding its treatment system for the next three years.

Methods. We used a statewide telephone drug use survey of 5,176 households supplemented by drug-related hospital discharges, Division of Drug Control statistics, and interviews with providers, state officials, and out-of-state experts. Drug abuse was measured with items from the Diagnostic Interview Schedule. Abusers were asked if they were receiving or wanted to receive treatment.

Results. Survey responses, used to estimate the unmet need for drug treatment, indicated a need to triple drug treatment services. Regression models using survey data indicated that the treatment network was overly centralized in the Providence area. Interviews with state officials, clinicians, and out-of-state experts provided material for recommendations on reimbursement policy, treatment mix, quality assurance, and cost containment.

Conclusions. The RI Department of Health's certificate-of-need program adopted our overall recommendation for tripling the drug treatment system as its guideline in evaluating proposals for new treatment facilities. With State funding of a new adolescent center and expansion of outpatient slots in the private sector, this recommendation has now been fully implemented. (*Am J Public Health* 1991;81:365–371)

Introduction

Recent federal and foundation initiatives on drugs and acquired immunodeficiency syndrome (AIDS) among intravenous (IV) users have led many states and communities to assess their needs for drug treatment services. Up to now, attempts to determine drug abuse treatment needs have lacked adequate tools. In the 1970s when substantial public funds for drug treatment first became available, planners based their needs assessments on census data, arrests, treatment admissions, and occupancy rates.[1,2] At best, however, such statistics represent only indirect approximations of addict prevalence and may be influenced by actions of the agencies that report the data.[3] For example, if services are too expensive, not well located, or not well matched to addict clinical or cultural needs, underutilization of treatment facilities may occur even when there is substantial unmet need for services in a state. The present study sought to develop improved methodologies.

In 1986, the Rhode Island Division of Substance Abuse (DSA) sought documentation of unmet need for drug abuse services to convince legislators of the necessity for third-party reimbursement of drug abuse treatment and to establish guidelines for regulators evaluating proposed treatment facilities. DSA had previously contracted with Brown University for a needs assessment of the combined alcohol and drug treatment system.[4] Although the Brown Report estimated drug use prevalence in Rhode Island from age- and gender-specific *national* rates reported in a 1982 survey of drug use by the National Institute on Drug Abuse (NIDA), the Report's authors recommended that a local drug abuse prevalence survey be conducted.

Several developments in the last two decades have made improved needs assessments possible for state and local agencies. In 1972, the federal government demonstrated the feasibility of household surveys of nonmedical drug use employing face-to-face interviews with a cross-section of the nation's population.[5] Some states (e.g., New York and New Jersey) have now initiated periodic household surveys of their own.

In 1981 and 1986, the New York State Division of Substance Abuse Services conducted a statewide survey of drug use by telephone interview.[6] A pilot study (1980) found that random digit dialing and a sample drawn from local telephone directories both returned response rates similar to those of a previous face-to-face survey of drug use (66 percent to 72 percent). Drug use rates in the statewide telephone survey were similar to those found in the 1979 NIDA face-to-face household survey, thereby confirming experiments which had found no significant difference between telephone and face-to-face responses to a variety of interview questions (see Discussion). Compared to personal interviews, telephone interviews represent an attractive approach for localities with limited budgets since telephone in-

terviews cost an average of half as much as face-to-face surveys using identical questions.[7]

Measures of drug *use,* however, have limited value in estimating the number of persons in the population who need treatment. Effective planning requires a measure of clinical levels of drug *abuse.* In 1981, Robins and her colleagues developed the Diagnostic Interview Schedule (DIS)[8] for epidemiological studies of mental disorders including alcohol and drug abuse. The DIS combines answers to questions on the frequency and consequences of use to form reliable scales of abuse and dependence that satisfy the American Psychiatric Association's formal (DSM-III) criteria for drug abuse and dependence.[9] Studies have demonstrated that the DIS can be used successfully in face-to-face household interviews,[10] and its use permits comparison with other populations already reported in the literature.[11] When DIS scores were compared with clinical diagnoses based on patient charts and DSM-III checklists, results showed moderate agreement (kappas for individual symptom scales ranged from −.01 to .63 with an average of .22 in one study[12] and .30 in another[13]).

Methods

The primary source of drug abuse data for this study was a telephone survey of Rhode Island households. The survey employed a proportional, stratified, multistage sample of persons age 12 or over living in households with telephones. The telephone numbers were identified by random digit dialing. A random sample of telephone numbers was drawn from each of the state's eight drug treatment catchment areas, with each area represented by a total proportionate to its share of the state population. Assuming a response rate similar to those found in previous New York State drug surveys (66 percent to 72 percent), we planned to use 7,000 of these numbers to reach the goal of 5,000 interviews. Interviewers asked to speak to the person in the household (12 years or older) with the most recent birthday; no substitutions were permitted.

The sample statistics were weighted[14] to produce representative parameter estimates for catchment areas and the state as a whole. Each respondent received an initial weight equal to the total number of persons age 12 or over in the household; the number of respondents in each catchment area was also weighted by the actual population size of the area. The weights were adjusted to correct for differences in response rate among catchment areas and multiplied by a constant to make the weighted sample size equal to the unweighted sample size of 5,176 completed interviews.

To increase community acceptance of the survey, all treatment and prevention agencies were notified about it and the Governor mentioned the study in his State of the State address. Several articles appeared in Rhode Island newspapers urging community cooperation.

We used the 1986 New York State drug survey[6] for basic drug use items and the Diagnostic Interview Schedule[8] for measures of abuse and dependence. We designed questions to measure *interest* in obtaining treatment. The final instrument was translated into Spanish for Spanish-speaking respondents.

Interviewers called each number in the sample until they succeeded in interviewing the designated respondent; determined that the number was either a business phone, had been disconnected or never assigned to a household by the telephone company; or reached the cut-off point of seven attempts. Interviewers made their first few calls in the evening (5:00 to 9:00); if these were not successful, they made further attempts on weekends. As a last resort, they tried calling on weekday mornings and afternoons. When a respondent refused to be interviewed, the survey supervisor arranged to have a more experienced interviewer try again several weeks later.

Reliability and Validity Studies

For 100 consecutive interviews conducted by several different interviewers, we compared the answers recorded by a supervisor listening on a remote monitor with the answers recorded by the interviewers. To estimate the potential bias of respondents who refused to cooperate, we compared the responses of persons (N = 130) who initially refused to respond but agreed to be interviewed when called again, to the responses of individuals who never refused. To estimate the potential bias of households that failed to answer the telephone, our research staff called all numbers not reached after seven attempts by the subcontractor. We then compared the responses of hard-to-reach individuals (the 92 reached by our staff) to those of respondents who were reached with seven or fewer calls. We also compared the sample demographics with census data.

To evaluate the truthfulness of respondents, we conducted a "randomized response" experiment in which a randomly selected subsample of respondents (N = 167) flipped three coins to determine whether or not to answer questions on drug use truthfully.[15] Since these respondents tossed the coins at home, interviewers could not tell whether the respondents were answering truthfully or just obeying the dictates of the toss ("yes" if all heads, "no" if all tails). Aggregate responses were statistically adjusted for expected frequencies. We then compared the resulting frequency of drug use reported by experimental subjects with the frequency of drug use reported by respondents in the general survey.

Drug Use and Abuse Measures

We estimated the percentage of lifetime and current moderate users, potential abusers and abusers. *Potential abusers* were respondents who reported "pathological" drug use (i.e. use of a drug daily for two weeks or more without a prescription) *or* that they had tried to cut down and failed to do so. *Abusers* were those who admitted to *both* pathological use *and* significant social impairment as a result of that use *or* to being drug dependent (showed signs of withdrawal and tolerance) whether or not they met the other two criteria.[8]

Computation of Unmet Demand

We defined the effective demand for drug treatment services as the number of services likely to be requested at current prices, assuming widespread knowledge of the availability of services and reasonable accessibility to them. We divided effective demand into *met demand* (the aggregate of clients enrolled in a drug treatment program at some time during the last twelve months) and *unmet demand* (the number of abusers who had not been in treatment during that period but who represented suitable candidates for admission). We asked all respondents who qualified as abusers by DIS criteria whether they were in treatment and, if not, whether they wanted treatment or at least had ever thought about entering treatment.

A conventional approach to estimating effective demand involves multiplying the estimated number of abusers in a population by a fixed percentage of abusers thought likely to seek treatment, the rule of thumb being 15 percent to 20 percent.[4] Using estimates of drug abuse prevalence from the telephone survey, we also estimated demand for treatment using this fixed percentage method.

TABLE 1—Validity Studies on Subpopulations

% Ever Used	Converted Refusals (n = 130)	Never Refused (n = 5046)	Difference (95% CI)	Hard to Reach (n = 92)	Not Hard To Reach (n = 5084)	Difference (95% CI)	Randomized Response* (n = 167)	Main Survey (n = 5176)	Difference (95% CI)
Marijuana	10.7	24.4	−13.7 (−19.2,−8.2)	29.7	24.0	5.7 (−3.7,+15.1)	28.0	24.1	3.9 (−3.0,+10.8)
Cocaine	3.0	7.3	−4.3 (−7.3,−1.3)	8.6	7.1	1.5 (−4.3,+7.3)	8.5	7.2	1.3 (−3.0,+5.6)
LSD/PCP	3.0	3.7	−0.7 (−3.7,+2.3)	3.0	3.7	−0.7 (−4.2,+2.8)	3.3	3.7	−0.4 (−3.2,+2.4)
Heroin	0.0	0.5	−0.5 (−0.7,−0.3)	0.0	0.5	−0.5 (−0.7,−0.3)	−7.5	0.5	

*Frequencies have been statistically adjusted for forced choice. The negative frequency for heroin use suggests that some respondents in the experiment could not bring themselves to say "yes" to having used heroin, even when the coin toss dictated that answer. The percent saying "yes" (6.9) was less than expected on the basis of chance alone. Subtracting the actual percent from the expected percent produced a negative number. Without additional data, that negative frequency is uninterpretable. Because the other three drugs showed no significant difference, it seems reasonable to conclude that the same was true for heroin.

Community Indicators of Drug Abuse

We analyzed established drug abuse indicators[16–18] to validate the telephone survey findings and to estimate optimal geographic distribution of services. Indicators were drug treatment admissions, hospital discharges (primary or secondary diagnoses of drug overdose, and so on), from the Rhode Island Department of Health, drug-related criminal complaints (suspected use, possession, or sales) from the Rhode Island Division of Drug Control, and drug arrests from the Federal Bureau of Investigation.

Allocating New Slots

We were asked to estimate the number of new treatment slots needed (if any), and to recommend how those slots should be distributed across both treatment modalities and catchment areas. To do so, we first looked at the drug use patterns of those respondents who said they wanted treatment now. Opiate users (who might be appropriate for methadone maintenance) were separated from users of other drugs. We then considered the current mix of treatment modalities in Rhode Island and used interviews with providers and state officials to identify gaps in modalities and levels of patient care. We also weighed the relative cost-effectiveness of different treatments. We estimated the optimal geographic distribution of admissions from their regression on survey drug abuse rates, criminal complaints, and hospital discharges.

Interviews with Providers and State Officials

A staff sociologist interviewed 38 drug program directors and state officials regarding current programs and problems involving client access, availability of services, AIDS, special needs, and other issues encountered in day-to-day operations, such as financing mechanisms, regulatory functions, relationships among agencies, and the continuum of care. To broaden our understanding of policy alternatives, we interviewed professionals from 13 states outside of Rhode Island.

The total cost (including indirect expenses) of the needs assessment was $150,000, of which our subcontractor received $50,000 ($10 per completed interview). The entire study (including a final report) took exactly six months to complete.

Results

Validity of Survey Findings

Of the 7,364 eligible households in the sample, 5,176 (70.3 percent) completed the interview. In the 100 consecutive cases where a supervisor coded responses independently of the interviewer, 99.3 percent of the responses were coded identically. Since most of the inconsistencies involved a question about friends' behavior, we excluded that item from further analysis.

Fifteen percent of those who initially refused to be interviewed eventually agreed to participate in the study. These 130 "converted refusals" reported *lower* frequencies of drug use and abuse than did those respondents who never refused (Table 1). The differences, however, were small except for ever-use of marijuana.

A comparison of 92 hard-to-reach respondents with those that were reached without extra effort revealed no significant differences in either drug use or abuse (Table 1).

The 167 respondents who were given the opportunity to disguise their answers in the "randomized response" experiment were no more likely to report illicit drug use than those in the general survey who were asked the same questions directly (Table 1).

A comparison of the survey sample with 1980 census figures for Rhode Island indicates close agreement on age, gender, and ethnicity.[19] A regression of catchment area drug abuse prevalence rates (measured by the survey) on drug-related hospital discharges and drug complaints provides further evidence ($R^2 = .89$) of the validity of the survey results.

Extent of Drug Use

Our survey yielded an estimated total of 13,948 current abusers, less than 2 percent of the state's 12 or older population of 793,334 (Table 2); 8,430 residents qualified as current potential abusers and 60,388 additional residents qualified as current minimal-to-moderate users. Approximately one-fourth of Rhode Island residents age 12 or older admitted to having *ever* used at least one illicit drug (marijuana, cocaine, LSD, or heroin) or licit psychoactive drug (sedative, amphetamine, or prescribed pain killer) without a prescription. The figure for *current* use (at least once in the past year) was 10.4 percent. Marijuana was used and abused more than any other drug, followed by cocaine, opiates, sedatives, amphetamines, and hallucinogens in that order.

Unmet Demand for Treatment

To determine unmet demand for treatment, we divided abusers not in treatment into a matrix of five levels of interest in treatment by three levels of the currency of abuse (Table 3). Analysis of the matrix generated 5,365 abusers (rows 1 and 2, and "recent" and "present abusers" in row 3) that made up the unmet demand for drug abuse treatment. We assumed that "past abusers" and "recent abusers" in row 1 were using currently

TABLE 2—Estimated Current Users, Potential Abusers, and Abusers, by Type of Drug

In Last Year	At Least One	Marijuana	Cocaine	Opiates**	Sedatives*	Amphetamines*	LSD/PCP
Users (Minimal or Moderate)	60,388	49,813	18,239	10,116	6,591	5,364	3,525

[c] Have abused in last month.

[d] Former drug clients who said "no" to wanting treatment now.

[e] Said "no" to wanting treatment now, have never been in treatment, but have considered treatment in past.

[f] Said "no" to wanting treatment now, have never been in treatment, and have never considered treatment.

but not at the point of abuse, or were in early recovery. The "not sures" in row 2 were included on the assumption that they would decide to enter a program if openings at the most sought-after services (methadone maintenance and short-term residential programs) were not in such short supply. Despite not wanting treatment now, the "present abusers" in row 3 were included because they had sought treatment before, had relapsed, but, we believed, would want treatment again were it readily available. The "recent abusers" in row 3 would similarly want intermediate care or aftercare. We excluded the respondents in row 3 who had not abused for over a year on the assumption that they were sufficiently recovered.

To get the total demand for treatment, we added unmet demand and met demand. Rather than estimating met demand from the number of survey respondents *currently* in treatment (which would exclude individuals discharged earlier in the year), we used actual MIS admissions (2,212) for the previous year. In this way, we estimated total effective demand to be 7,577 in 1986. We recommended that Rhode Island should expand its treatment system until it could accommodate all 7,577.

According to the traditional rule of thumb for estimating the number of addicts who will avail themselves of treatment at any one time, there were 2,789 Rhode Island residents (20 percent of the estimated 13,948 current drug abusers in the State) who were candidates for drug abuse treatment at the time of our study. This estimate suggests that if Rhode Island were to provide treatment for all addicts who wanted it, it would have to expand its services by 26 percent (from 2,212 to 2,789) as opposed to the 243 percent expansion (2,212 to 7,577) indicated by the first method.

Expansion of Services

Given the State's fiscal constraints and siting difficulties for new facilities, we recommended that the expansion of services be divided into two phases. In phase I (two to three years) the State would add enough slots to accommodate the estimated 2,150 abusers who said in the telephone interview that they wanted treatment right now (all abusers from row 1). Adding 2,150 admissions would nearly double the present treatment system. In phase II, which would extend for several years beyond phase I, the State would add enough slots to accommodate the remaining 3,200 abusers (all abusers from row 2 and most from row 3) whom we deemed likely applicants for new treatment slots but whose desire to enter a program immediately was less definite under present conditions. A phased expansion would allow for adjustments if drug abuse indicators suggested substantial changes in addict prevalence during phase I or if our conclusions about demand for services were not borne out by experience.

For most treatment modalities, we recommended making phase I increases proportionate to the number of slots already in existence. We assumed that the mean number of admissions per slot would remain constant in the future and that the current mix of services reasonably reflected the demand for different types of services. We suggested a somewhat larger expansion for methadone maintenance programs, however, because half of the abusers who said they wanted treatment reported heroin addiction, and because, at the time of the study, there was a two-year waiting period at the State's only methadone center. We also recommended adding a small number of residential 28-day drug treatment slots and a still smaller number of outpatient narcotic antagonist (Naltrexone) slots[20,21] to serve the opiate addicts. Neither of these latter two modalities formally existed in Rhode Island at the time of the study.

To guide geographic distribution of new treatment slots, we regressed treatment admissions on a weighted index of drug-related hospital discharges, drug-related complaints to the Division of Drug Control, and our survey results on the number of drug abusers in each catchment area. For outpatient drug-free admissions (including day treatment), the regression of treatment capacity on the weighted index of hospital discharges, drug complaints, and abusers revealed in the survey yielded an R^2 of .55. The results (Figure 1) confirmed the opinion expressed by some officials that treatment facilities were overly concentrated in central regions of the state. We recommended that proportionately more new admissions should be added according to the discrepancy between actual and expected number of slots.

To determine where new methadone slots should be sited, we performed a similar regression analysis and comparison using opiate admissions as the dependent variable and opiate use as reported in the survey as the independent variable. In the case of short-term (28 day) and long-term (therapeutic community) residential modalities where the number of existing slots was too small and concentrated for a regression analysis, we adopted the rule of thumb that the State should locate new slots in areas that presently had no residential facilities for drug abusers. This made sense in light of the survey finding that there were significant numbers of drug abusers in every catchment area.

Interview Results

Providers and state officials were in agreement that the primary problem was the inadequacy of treatment capacity. While providers stressed shortage of staff and low salaries, state officials stressed the need for mandation of third-party reimbursement of substance abuse services, quality assurance, and greater access to treatment for subpopulations such as adolescents and the poor. We used these interview results in recommending increased funding and new mechanisms for improving utilization of existing funds (revision of traditional lengths of stay and establishment of a statewide panel to review treatment practices). Interviews with policymakers in other states provided us with valuable information on some of the problems to be expected with third-party mandation such as changes in the number of drug abusers seeking care and increases in premium cost. We also recommended for-profit programs and "medical maintenance"[22] for increasing methadone slots in the face of limited public allocations.

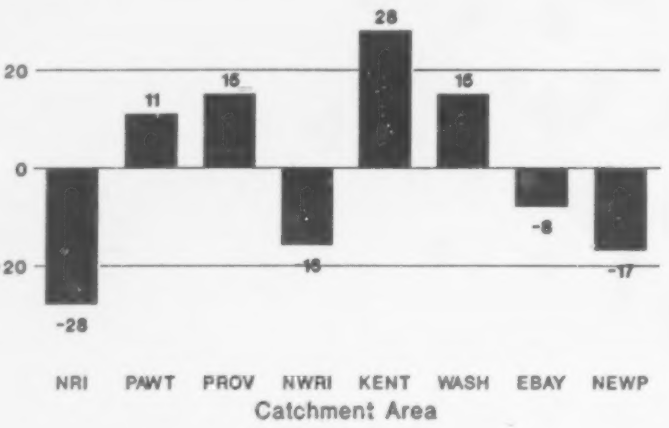

FIGURE 1—Adequacy of treatment allocation: Actual minus expected number of OPDF slots,* by catchment area.

*Estimated by statistically regressing OPDF slots on an index made up of: 1) current abuse rate of *any* drug; 2) number of drug-related hospital discharges; and 3) number of complaints reported to the RI Division of Drug Control (OPDF Slots = .67 + .07 (Drug Problem Index).

Reaction to Recommendations

The initial reaction to our report was mixed. In a series of hearings and written statements, most state officials praised it.[19] Third-party payors supported the report's recommendations for reduced lengths of stay and a higher ratio of outpatient to inpatient treatment, while objecting to its endorsement of mandatory drug treatment benefits (several months before we submitted our final report, the Rhode Island legislature had mandated third-party coverage for drug abuse treatment). Providers were "particularly impressed with the depth of the household survey and the methodology used to determine effective demand for treatment,"[19] but felt that we had paid too much attention to cost containment and quality regulation.

The Division of Substance Abuse, its parent organization, the Department of Mental Health, Retardation and Hospitals, and the Department of Health endorsed our recommendation that the drug treatment system be doubled in the next few years. In the year following submission of our report (1988), the State provided $700,000 for new methadone maintenance slots and another $3,900,000 for the construction and operation of a 60-bed adolescent treatment facility which our report had recommended. Private agencies added 300 methadone slots, 600 outpatient drug-free slots, and 60 28-day residential treatment slots. With the exception of the $700,000 for methadone maintenance and the projected adolescent facility, all of the expansion was funded by the private sector. By July 1989, the State's drug treatment network had expanded to levels close to those recommended for phase I of the expansion.[23] Methadone slots had reached 75 percent of the phase I target with a concomitant decrease in waiting lists. Outpatient drug-free slots had exceeded the phase I target and were already approaching the level we had recommended for phase II. The number of inpatient 28-day slots had already surpassed the phase II target.

The only major drug treatment modality to lag behind in the expansion was long-term residential care (therapeutic communities), the primary form of treatment excluded from the 1987 bill making third-party insurance coverage of drug abuse treatment mandatory throughout Rhode Island. In our follow-up report integrating findings from the Brown (alcohol) and Harvard (drugs) reports, we made a special plea for legislation to correct this omission.*

*McAuliffe WE, Lewis D, Breer P, Williams C: *Rhode Island integrated alcohol and drug treatment program matrix*. Cranston, Rhode Island: Division of Substance Abuse, Rhode Island Department of Mental Health, Retardation and Hospitals, unpublished report.

Throughout the expansion of the treatment network, the State exerted a continuing influence through its control over the certificate of need (CON) process. Once the Department of Health and related departments approved our recommendations, the State Health Planning Committee formally adopted the report's treatment slot recommendations as a guide in evaluating applications for new treatment facilities (both private and state funded).

Discussion

The percent (25) of Rhode Island residents age 12 or older who reported using illegal drugs at some point in their lives agrees with the results of national studies[24,25] and studies of nearby states.[6] Estimating the effective demand for drug treatment from survey results produced a figure almost three times as large as the total estimated by the fixed percentage method which assumes that only 20 percent of all abusers will seek treatment, the major difference stemming from our discovery of past abusers who want treatment and former clients who are currently abusing. The validity of the larger estimate is supported by the fact that Rhode Island doubled its treatment slots in the two years following submission of our report[23] and has thus far reported no difficulty filling those new slots.

The validity of estimating drug use and abuse by interview surveys has been studied since the 1960s. Measures of drug-use frequency have shown high internal and test-retest consistency among both addicts and non-addicts.[26,27] Surveys of special populations (addicts in treatment,[26,28–32] psychoactive prescription drug users,[33] Vietnam military returnees,[34] and addicts once known to the police[35]) have successfully corroborated interview statements of drug use with official records, family members, treatment personnel, and urinalysis results. Arrestees awaiting trial[36] are one group known to underreport substantially their use of illicit drugs.

There is both direct and indirect evidence that drug use survey responses in general populations are also reasonably valid.[37] The most direct evidence comes from use of the "randomized response" technique.[38] Respondents who are given a chance to conceal their true answers from the interviewer have generally reported levels of drug use equal to or only slightly higher than those of respondents asked to state their answers openly.[15,39] Indirect evidence can be found in the similarity of drug-use rates reported by different investigators studying independent but demographically comparable segments of the population.[37] Further support for the validity of drug-use questionnaires comes from the finding that, when respondents are asked about fictitious drugs, only a small fraction report any use.[40–42]

Studies comparing telephone survey responses with those of face-to-face interviews have generally found the results to be similar.[43,44] A recent study[45] found, however, that compared to face-to-face interviewing, telephone interviewing yielded significantly lower estimates of marijuana use among Blacks. The differential persisted after controlling for demographic differences between the two samples and excluding non-telephone households, suggesting that it had something to do with the mode of interviewing itself. However, the difference in rates did not hold for Whites, nor did it hold for cocaine use among either Blacks or Whites. Other controlled drugs were not tested. If there is a biasing effect in telephone interviewing, it is very limited and unlikely to affect overall prevalence rates of drug use and abuse in general surveys, particularly in surveys of states like Rhode Island with small minority populations.

Thus, research on drug surveys in general and telephone interviewing in particular suggests that under ordinary circumstances respondents tell the truth about their drug use. Where systematic bias occurs, it is typically in the direction of underreporting the frequency of drug use.[37,42] It follows that a treatment needs assessment based on community prevalence estimates of drug use and abuse tells us the *minimum* number of slots needed if the community is to make treatment available to all who need and would seek it. As for our own survey, several indicators discussed earlier suggested that the findings have acceptable reliability and validity.

One of the drawbacks of the household survey is that it yields proportionately few individuals who qualify as drug abusers. In our sample, less than two percent met criteria for drug abuse, and less than three-tenths of 1 percent expressed interest in getting treatment. To enlarge the base of abusers in order to investigate detailed planning issues, we suggest employing a larger total sample or, where cost considerations rule that option out, oversampling geographic areas known by arrests and hospital data to contain many drug addicts.

A drawback specific to the telephone drug abuse survey is that it excludes a subpopulation (households without a telephone) likely to have a high prevalence of drug abuse. This population, however, is quite small. In 1981, 98 percent of Rhode Island households had telephones.[46] Intravenous drug users (IVDUs) are a subgroup of drug abusers that one might expect to have the lowest telephone rates of all. In nearby Massachusetts, unpublished data from our current multi-city study of IVDUs (N = 577) not in treatment who were recruited through street outreach, indicates that 84 percent either have their own phone (38 percent) or have access to a phone at their current residence (46 percent).

Another limitation of any household survey, whether telephone or face-to-face, is that it excludes both the homeless and the institutionalized (prisoners, psychiatric patients, college dorm residents). The prevalence of drug abuse is known to be higher in these populations than in the general household population.[47] New York State's Division of Substance Abuse has recently developed a strategy for surveying the homeless, utilizing prearranged telephone interviews with randomly chosen residents of urban shelters.[47] In many states, drug treatment services for prisoners and psychiatric patients are provided by agencies other than the drug treatment agency and therefore may not be included in a needs assessment.

A recent US Senate report recommended improving upon survey estimates of cocaine abuse prevalence by adding nonsurvey data on nonhousehold populations (arrestees, drug patients, and the homeless).[48] Although we believe that the report's methodology may over-correct survey estimates, the report actually estimated *fewer* cocaine addicts in Rhode Island (3,900) than we estimated from our telephone survey (4,300).[19]

The orderly expansion of treatment services in Rhode Island testifies to the effectiveness of the needs estimation methods used in the present study. With improvements in survey methodology, statistical techniques, and the development of standardized diagnostic instruments suitable for testing large populations, substance abuse planning technology has entered a new era. It is reasonable to expect further progress in years to come. □

Racial/Ethnic Differences in Smoking, Drinking, and Illicit Drug Use among American High School Seniors, 1976–89

Jerald G. Bachman, PhD, John M. Wallace, Jr., MA, Patrick M. O'Malley, PhD, Lloyd D. Johnston, PhD, Candace L. Kurth, MPH, and Harold W. Neighbors, PhD

ABSTRACT

Background. This paper reports racial/ethnic differences in the use of licit and illicit drugs by high school seniors in the United States.

Methods. The study uses questionnaire data from annual, nationally representative surveys of seniors from 1976 through 1989. Combined sample sizes were 57,620 for 1976–79; 75,772 for 1980–84; and 73,527 for 1985–89.

Results. Native Americans had the highest prevalence rates for cigarettes, alcohol, and most illicit drugs; White students had the next highest rates for most drugs. Asian Americans had the lowest prevalence rates, and Black students had levels nearly as low except for marijuana. Prevalence rates for the Hispanic groups were mostly in the intermediate ranges except for relatively high cocaine use among the males. Trend patterns for most forms of drug use were similar across subgroups, although cigarette use declined more sharply for Black than White seniors, resulting in greater Black-White differences in recent years.

Conclusions. This study, other school-based studies, and general population surveys all show relatively low levels of drug use by most non-White youth, especially Black Americans and Asian Americans. Multivariate analyses indicate that such subgroup differences in high school seniors' drug use are not primarily attributable to family composition, parents' education, region, or urban-rural distinctions. (*Am J Public Health* 1991;81:372–377)

Introduction

Drug use among American youth continues to be a focus of attention for politicians, educators, the media, and the general public. Although the media frequently focus on large cities, the nation's drug problems are not limited to any one group or to any one geographic area. The impacts of drug use and abuse are felt more keenly in the Black, Hispanic, and Native American communities,[1] but the patterns of drug use by members of these groups, particularly adolescents, are not well documented. The purposes of the present report are: to document the extent to which drug use varies among racial/ethnic subgroups of high school seniors; to explore whether subgroup differences have been changing in recent years; and to consider some of the implications of such differences.

The data reported here are based on samples of high school seniors, representative of the United States as a whole. The study does not undertake to explore substantial differences in drug use which may exist from one city to another, or from one neighborhood to another. More importantly, surveys of high school seniors do not include those youth who drop out before graduation; thus, although this report represents most young people, including the majority of those in each racial/ethnic subgroup studied, it does not cover the total cohort of 17- to 18-year-olds. These limitations are treated at some length in the discussion.

Methods

The Monitoring the Future project, conducted by the University of Michigan's Institute for Social Research under grants from the National Institute on Drug Abuse, has surveyed large, nationally representative samples of high school seniors during the spring of each year since 1975. The design and procedures are summarized briefly below; detailed descriptions are presented elsewhere.[2-4] The measures of drug use and racial/ethnic identification are presented in the Appendix.

Samples

A three-stage sampling procedure is employed,[5] with stage 1 the selection of particular geographic areas, stage 2 the selection of one or more high schools in each area, and stage 3 the selection of seniors within each high school. The result each year is an area probability sample of the 48 coterminous states. About 130 high schools participate each year (approximately 118 public and 12 private). About 83 percent of the sampled seniors generally participate (nearly all nonparticipation results from absenteeism), yielding samples of about 17,000 seniors each year.

Survey Procedures

Data are collected via questionnaires administered in classrooms by locally based Institute for Social Research representatives and their assistants, following carefully standardized procedures. The questionnaires are designed for optical scanning; all items are closed-ended. Five different questionnaire forms have been

TABLE 1—Racial/Ethnic Distribution of the Monitoring the Future Combined Samples*

	1976–79		1980–84		1985–89	
	N	%	N	%	N	%
White	48993	85.0	62157	82.0	57864	78.7
Black	5965	10.4	8958	11.8	8187	11.1
Mexican American	1088	1.9	1480	2.0	3117	4.2
Puerto Rican/Latin American	572	1.0	1105	1.5	1392	1.9
Asian American	439	0.7	1139	1.5	1899	2.6
Native American	563	1.0	933	1.2	1068	1.5
Total	57620	100.0	75772	100.0	73527	100.0

*The multistage sampling design with respondents clustered in schools produces larger sampling errors than would a simple random sample of equivalent size. For statistics in the present paper, the estimated design effects are 8.0 for White males and females, 3.0 for Black males and females, and 2.2 for the males and females in any of the other groups. Frequencies used to calculate statistical significance are equal to the actual number of cases shown in the table divided by the appropriate design effect (i.e., 8.0, 3.0, or 2.2). When referring to group differences the term "significant" or "significantly" refers to $p < .01$.

used each year, with each administered to a random one-fifth of the sample.

Statistical Significance and Confidence Intervals

Confidence intervals vary greatly depending upon sample size, design effects (see note to Table 1), and percentage size. As examples and general guidelines, we note the following: The *largest* 95% confidence intervals around percentages in Tables 2–4 are 1.7 percent for Whites, 2.8 for Blacks, 3.7 for Mexican Americans, and 6.3 for Native Americans (the smallest subgroup). Any Black-White difference equal to or exceeding 3.0 percent is significant at the 95% confidence level. It would be unnecessarily cumbersome to specify significance levels for every subgroup comparison discussed herein; instead, we have adopted the convention of describing *as differences* only those which exceed the 99% confidence level.

Results

Our primary emphasis is upon racial/ethnic subgroup differences in drug use, especially those which have been somewhat consistent across time. We examined annual data from the senior classes of 1976 through 1989, combining the classes into three groups: 1976–79, 1980–84, and 1985–89. The resulting numbers of cases for the total samples and the racial/ethnic subgroups are displayed in Table 1.

Table 1 indicates that the proportions of Whites in the samples decreased over time, whereas the proportions of Asian Americans and Hispanics increased substantially. These changes generally parallel shifts in the overall population of youth, although it should be kept in mind that the proportions in our samples reflect some substantial subgroup differences in high school dropout rates, as well as other differences (including a somewhat higher rate of missing data for several of the subgroups other than White). In particular, it should be noted that nationwide dropout rates for Blacks have declined in recent years, and are now only slightly higher than those for Whites.[6]

Subgroup Differences in Prevalence of Drug Use

Marijuana

Annual prevalence rates for marijuana (1985–89 combined; see Table 2) are highest among Native American females and males, and nearly as high among White males and females, and Mexican American males; rates are somewhat lower for Mexican American females, Puerto Rican and other Latin American males, and Black males; and rates are lowest among Puerto Rican and other Latin American females, Black females, and Asian American males and females. Monthly and daily (or nearly daily) prevalence rates for marijuana show similar subgroup distinctions, except that male-female differences are more pronounced (Tables 3 and 4).

Cocaine

Prevalence rates for cocaine are highest for Native Americans (males and females) and males in both Hispanic groups, but significantly lower for Hispanic fe-

Daily	7.0	4.2	8.3	4.0	2.3	10.1	2.8	0.7	2.6	0.9	0.9	5.4
5+ drinks in a row/last 2 weeks	48.1	24.0	45.3	31.4	19.4	48.1	31.3	9.3	23.6	14.5	10.7	33.7
Cigarettes	18.8	8.6	11.6	13.3	9.0	26.0	22.5	7.1	8.1	13.3	9.4	33.8
Half-pack or more per day	12.5	3.3	5.2	6.1	4.4	18.4	13.3	2.2	2.5	4.2	4.5	23.4

males; rates for Whites are fairly similar to those for Hispanics, except that the difference is somewhat smaller between males and females; and rates are significantly lower for Blacks and Asian Americans. In the case of Asian Americans, prevalence rates for males and females are essentially the same; however, for Blacks, like Hispanics, the prevalence is about twice as high for males as for females.

Other Illicit Drugs

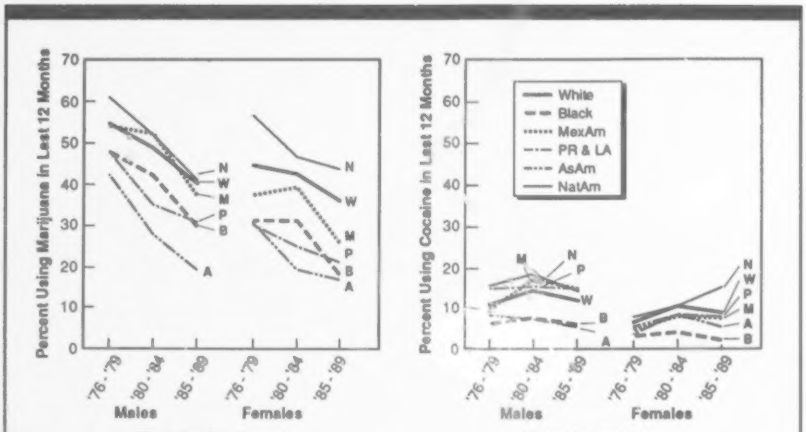
Tables 2 and 3 provide details on a number of other illicit drugs: inhalants, hallucinogens, heroin, other opiates, stimulants, sedatives, and tranquilizers (any use under doctor's orders is excluded). For most drugs and most subgroups, fewer females than males report use, with usage rates being highest for Native American seniors, and lowest for Black and Asian American seniors. Differences among White and Hispanic seniors are generally smaller and not consistent across these other illicit drugs.

Alcohol

Alcohol use among White and Native American males and females is relatively high, while among Black and Asian American seniors, only about half of the males and one-third of the females report use of alcohol during the past month. Substantial subgroup differences exist in frequent or heavy use of alcohol (i.e., five or more drinks in a single sitting). As shown in Table 4, almost half of White, Native American, and Mexican American males report such heavy alcohol use once or more during the two weeks preceding the survey. Heavy drinking is significantly less prevalent among Puerto Rican and other Latin American males, and even lower among Black males and Asian American males. Racial/ethnic differences among females generally parallel those for males, but at distinctly lower prevalence levels. Although relatively few seniors drink alcohol on a daily or near daily basis, this behavior shows subgroup differences which parallel those for heavy drinking (Table 4).

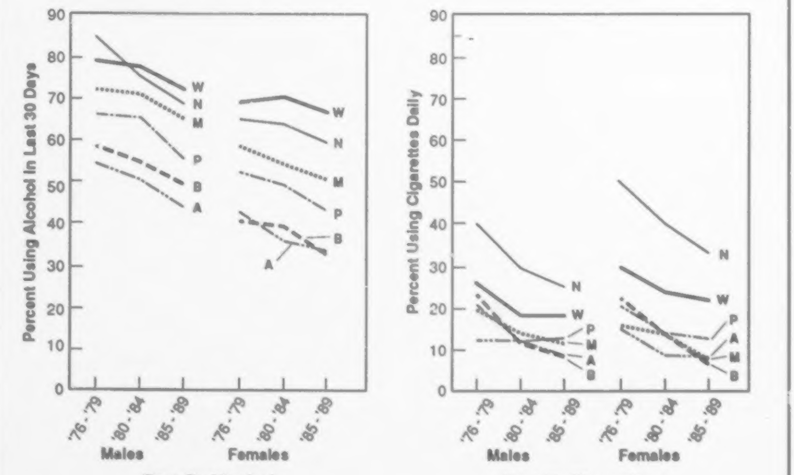
Cigarettes

About two-thirds of all seniors have tried cigarettes sometime in their lives;[2] however, the much more important measures are those reflecting their current behavior: monthly prevalence (Table 3), and especially daily prevalence and half-pack-a-day use (Table 4). Half-pack daily use is highest among Native American seniors, significantly lower among Whites, and far lower among the other subgroups. In contrast to most other drugs, cigarettes have been used just as much by young women as by young men in recent years.



Part A: Marijuana

Part B: Cocaine



Part C: Alcohol

Part D: Cigarettes

FIGURE 1—Trends in Use of Four Drugs, 1976–89, by Sex and Race

Trends in Prevalence of Drug Use, 1976–89

There have been a number of important increases and decreases in the use of various drugs since the mid-1970s, as we have reported in detail elsewhere.[2,7] Our purpose here is to consider whether some of the most important racial/ethnic subgroup distinctions observed in the classes of 1985–89 are relatively long-standing ones or reflect recent changes.

Illicit Drugs. Part A of Figure 1 shows that the downward trend in annual marijuana use occurred within all subgroups, and that subgroup differences were fairly consistent across time. Part B of Figure 1 shows the overall rise in cocaine use between the late 1970s and the early 1980s; the patterns of subgroup differences are not so consistent across time, but because of the generally small proportions of cocaine users we cannot be very confident in asserting different subgroup trends across time. Use of most of the other illicit drugs shown in Tables 2 and 3 declined during the past decade[2]; here again, the generally low proportions of users provide little basis for asserting *differential* subgroup trends across time. (Data for the earlier time periods are presented elsewhere.[8])

Alcohol. As Part 3 of Figure 1 indicates, 30-day prevalence of alcohol use has declined somewhat, especially among males, but subgroup differences were largely consistent across time.

Cigarettes. As shown in Part D of Figure 1, prevalence rates for daily use of cigarettes have declined for all subgroups. Substantial declines occurred between 1976–79 and 1980–84, whereas declines in recent years have been much smaller. Some groups (e.g., White males) showed no decline in recent years. In general, the declines in smoking have been stronger among non-White groups. Most notably, daily smoking prevalence rates of Black seniors dropped by two-thirds (from 23.6 percent to 8.6 percent for males, and 22.3 percent to 7.1 percent for females). Thus, Black-White differences in cigarette smoking have become more pronounced in recent classes of high school seniors.

Discussion

Although relatively little research compares drug use among racial/ethnic subgroups, the existing studies[7,9–20] yield a fairly consistent set of findings: Asian American youth tend to report very low levels of drug use relative to other groups. Black youth consistently report lower rates of drug use than White youth. Hispanic youth typically report more substance use than Blacks and only slightly less than Whites. Native American youth on average report greater use of alcohol and other drugs than any other subgroup.

The present findings are largely consistent with the literature. One contribution of the present research has been to document these differences based on large, nationally representative samples of high school seniors. Another contribution has been to demonstrate that for more than a decade the racial/ethnic subgroups have shown parallel trends, for the most part, in their use of alcohol and the illicit drugs. An important divergence in smoking rates (smaller declines among Whites) also has been noted.

Several important questions remain. First, are these replicated (and thus *reliable*) findings of subgroup differences also *valid*? In other words, how accurate are young people's self-reports of drug use in general, and are there reasons to suppose that subgroups may differ in accuracy? Second, how do the subgroups differ in dropout rates, and how do these differences affect our ability to generalize to total age cohorts? These are issues which have concerned us for some time, and they have made us cautious about reporting subgroup differences in drug use.[4] Although we have not fully resolved these questions, we have become increasingly confident that the subgroup differences reported here are, on the whole, valid.

First, with respect to self-reports of drug use, there is a growing literature indicating their validity.[21–25] Some questions may remain, of course, about the willingness of seniors to report their drug use honestly if they are not confident about the purposes of the research, if they do not trust the survey administrators, and/or if they have greater than average tendencies toward favorable self-presentation. Mensch and Kandel report that in the National Longitudinal Survey of Youth, which employed face-to-face interviews, Black and Hispanic youth were more likely than White youth to underreport their use of marijuana; however, this underreporting occurred most often at the lowest levels of use.[26] Incidentally, their initial analyses (based on total samples) revealed no underreporting of the licit drugs (i.e., alcohol and cigarettes), which show the largest subgroup differences in the present study.

Earlier analyses of Monitoring the Future data[8] revealed subgroup differences in rates of missing data and inconsistent responses; however, these differences do not parallel the subgroup differences in self-reported drug use. For example, Native American seniors have relatively high rates of missing data and/or inconsistent responses (6.6 percent for marijuana) as well as high self-reported drug use, whereas Black seniors have equally high rates of missing data and/or inconsistent responses (6.8 percent for marijuana), but much lower self-reported drug use. White and Asian American seniors are fairly similar in having low rates of missing data and/or inconsistent responses (2.3 percent and 3.1 percent, respectively, for marijuana), but their rates of drug use are distinctly different.

Additional analyses of Monitoring the Future data have shown that Blacks are more likely than Whites to perceive that drug use involves high risks, and to disapprove of drug use. Black seniors also are much less likely to report smoking, alcohol use, and drunkenness by friends, consistent with the large Black-White differences in self-reported drug use.* It is hard to imagine that these complexly interrelated findings are simply the result of selective distortion; in particular, it is unlikely that such distortion would result in much larger differences in self-reported use of the licit drugs compared with the illicit drugs. We find it more parsimonious to conclude that the substantial Black-White differences in self-reports are largely the result of genuine differences in drug use between our samples of Black and White high school seniors.

Even if self-reports are mostly valid across all of the subgroups studied, we are faced with further questions because our surveys do not include young people who drop out of high school before late spring of their senior year. Given that drug use is generally higher among dropouts, how different would findings be if based on the total cohort of 17- to 18-year-olds rather than just high school seniors? It is highly likely that the inclusion of dropouts would tend to raise the observed prevalence rates for all drugs and all subgroups. In addition, it seems fairly likely that the impact would be greatest in subgroups with high dropout rates, thus changing subgroup comparisons in several respects. First, Hispanics have higher than average dropout rates;[6] therefore, comparisons of *all* White and Hispanic 17- to 18-year-olds would probably yield somewhat smaller differences in drug use than found in samples of seniors. Second, Asian Americans have lower than average dropout rates[6]; accordingly, this subgroup might be even farther below average given drug use data based on the total age cohort rather than just seniors. Third, given the very high dropout rates among Native Americans,[6] total age cohort data might place them even farther above average in drug use. Fourth, Black-White differences in drug use might be reduced if we compared the total age cohort rather than just seniors; however, because Black and White dropout rates are now fairly similar,[6] the reduction would not be very large, unless drug use is differentially correlated with dropping out. It is also worth noting that recent household surveys, which do not omit dropouts, find Black-White differences in youthful drug use roughly as large as those reported here.[7]

If drug use really is lower than average among most non-White youth, an interesting question remains as to why this occurs. Multivariate analyses reported elsewhere[8] indicate that it cannot be attributed primarily to differences in parental presence or education, nor does it have a great deal to do with where seniors live throughout the United States. Some other dimensions of lifestyle we have measured have more bearing on drug use, but they do not account for most of the subgroup differences in use—especially the very low rates of cigarette and alcohol use by Blacks. Other possibilities which we have begun to explore, and will continue to examine, are that these relatively low usage rates are strongly influenced by particular religious doctrines and affiliations; differences in parent, peer, and community norms; different attitudes regarding the use of drugs; or differing levels of perceived risk.

The very low rates of drug use (particularly cigarette use and alcohol use) by Black students may be surprising, in light of evidence that drug-related mortality and morbidity are higher among Black than White adults.[1] These contrasting findings are, however, consistent with data from national household surveys comparing Blacks and Whites at various age levels: Black youth show much lower usage rates than White youth; in early adulthood differences are smaller; and by middle adulthood, the drug use/abuse rates are often higher among Blacks.[7,27,28]

It has been observed that "two worlds" of drug use (particularly alcohol use) exist within the Black community: the extremes of abstinence at one end and heavy use/abuse at the other.[27,29] As a result of heavy drug use by a minority (often having limited financial resources, health care, and insurance), Black adults are disproportionately represented in morbidity and mortality statistics, and data from public treatment centers. Such data, rather than findings from general population surveys, often serve as the basis for

Appendix

Measures

The use of alcohol and the use of each of the illicit drugs are measured by questions having the following format: On how many occasions (if any) have you used [name of drug category] . . .

a) . . . in your lifetime?

b) . . . during the last 12 months?

c) . . . during the last 30 days?

Seven response categories are available: 0 occasions; 1–2; 3–5; 6–9; 10–19; 20–39; 40 or more occasions. Annual and monthly prevalence refer to any use of the specific substance during the last 12 months, or the last 30 days, respectively. Daily prevalence refers to use on 20 or more occasions in the last 30 days. An additional question about heavy use of alcohol asks respondents how many times in the last two weeks they had five or more drinks in a row. Cigarette use is measured by a question which asks about use in the past 30 days (none, less than 1 cigarette per day, 1–5 cigarettes per day, about ½ pack per day, about 1 pack per day, about 1½ packs per day, 2 or more packs per day). There is a good deal of inferential data in support of the validity of such self-report measures of drug use, summarized elsewhere.[2,21-25]

The measure of racial/ethnic identification is based on the questionnaire item: "How do you describe yourself? 1. American Indian; 2. Black or Afro-American; 3. Mexican American or Chicano; 4. Puerto Rican or other Latin American; 5. Oriental or Asian American; 6. White or Caucasian; 7. Other."

conclusions about drug use among Black Americans. Our present findings clearly suggest that such data bases are too limited, and can yield a false picture of the subgroup as a whole.

But it is equally true that general population surveys do not provide an adequate basis for generalizations about the full range of drug use problems among Blacks, Whites, or any other racial/ethnic subgroup. Persons in drug treatment, the homeless, and those in prison are not represented in general population surveys. Additionally, dropouts, youth who are chronically absent, those in juvenile detention centers, and those who are homeless, are not well represented in samples of high school students. Here again, because minority group members make up disproportionate shares of most or all of these "high risk" populations, and because the levels of drug use in these populations are greater than average, it is widely believed that drug use is more pervasive among minorities than among Whites. While that remains a possibility among the dropouts, it now seems quite unlikely among young people who complete high school.

In sum, we are confronted with (at least) two worlds of drug use *data*. On the one hand, the findings from general population and school-based surveys clearly and consistently show relatively low levels of drug use by most non-White youth, especially Black Americans and Asian Americans. On the other hand, the public health statistics on mortality, morbidity, and treatment provide a somewhat different perspective. So perhaps our most important conclusion must be that neither form of data provides a complete picture of drug use. However, that should not overshadow the other important conclusion: the majority of non-White youth do complete high school, and among most of these individuals, usage rates for both illicit and licit drugs are lower than average. ☐

Elevated Nicotine Levels in Cervical Lavages from Passive Smokers

Carol J. Jones, PhD, Mark H. Schiffman, MD, MPH, Robert Kurman, MD, Peyton Jacob III, PhD, and Neal L. Benowitz, MD

ABSTRACT

One hundred forty-five nonsmokers found to have normal cytologic diagnoses on routine Pap smears were interviewed regarding environmental exposure to tobacco smoke, and a 3 ml saline lavage of the cervix was collected for measurement of cervical nicotine levels by gas chromatography-mass spectroscopy. Nicotine levels tended to be highest among women exposed to tobacco smoke in the home, intermediate in women exposed only outside the home, and lowest in women recalling no exposure ($p = 0.001$). (*Am J Public Health* 1991;81:378–379)

Introduction

Women exposed to environmental tobacco smoke show biochemical evidence of smoke absorption in their saliva, serum, and urine.[1] A study of four women[2] recently reported that the cervical mucus of passive smokers might contain nicotine and its major metabolite, cotinine, concordant with the finding of increased concentrations of nicotine and cotinine in the cervical mucus of active smokers.[3,4] To confirm this report, we measured the concentrations of nicotine in cervical lavages taken from 145 cytologically normal, nonsmoking women, comparing concentrations in women passively exposed to tobacco smoke with those not exposed.

Methods

Subjects were part of a larger study of cervical neoplasia conducted in three Washington, DC area hospitals.[5] One hundred forty-five nonsmokers found to have normal cervical cytologic diagnoses on routine Pap smears were interviewed regarding environmental exposure to tobacco smoke, and a 3 ml saline lavage of the cervix was collected as previously described.[4] The interview included questions on the following topics: exposure to environmental tobacco smoke inside and outside the home in the previous 24 hours, time since last exposure, number of active smokers in the home, the smokers' relationship to the subject, and their usual intensity of smoking and products smoked (cigarette, cigar, pipe). The questionnaire focused on the 24 hours preceding specimen collection because previous research had indicated that cervical nicotine levels were correlated with active smoking during this period.[4] Specimens were kept frozen at −70° C until tested. All laboratory analyses were performed without knowledge of the smoking histories.

Nicotine was extracted from lavage samples by a modification of a published procedure.[6] The extracts were analyzed by combined gas chromatography-mass spectroscopy,[7] using a stable isotope-labeled analog, nicotine-d_4, as an internal standard. As a quality control measure, 17 aliquots of a pool composed of 19 cervicovaginal saline lavages, 17 from nonsmokers and two from smokers, were included among the specimens to be analyzed, with labels indistinguishable from the test specimens. The quality control data suggested that nicotine was measured reliably in the lavages. The mean of the 17 replicate measurements was 2.72 ng/ml with a coefficient of variation of 13.6 percent and a range of 2.2–3.5 ng/ml.

To classify subjects with regard to environmental tobacco smoke exposure, the following categories were formed: group 1 included women who reported exposure inside their homes within the past 24 hours, group 2 was comprised of women reporting exposure only outside their homes within the past 24 hours, and group 3 included women who recalled no exposure to environmental tobacco smoke in the previous 24 hours.

This paper, submitted to the Journal December 15, 1989, was revised and accepted for publication September 5, 1990.

TABLE 1—Nicotine Levels in Cervical Lavages from 145 Nonsmokers, according to Exposure to Environmental Tobacco Smoke over the past 24 Hours

Nicotine level (ng/ml)	Group 1 (exposed at home)		Group 2 (exposed only outside home)		Group 3* (not exposed)	
	#	%	#	%	#	%
<0.2	5	15.6	6	14.3	22	31.4
0.2–0.3	7	21.9	14	33.3	21	30.0
0.4–0.7	4	12.5	10	23.8	20	28.6
>0.7	16	50.0	12	28.6	7	10.0
Total	32	100.0	42	100.0	70	100.0

Chi-square = 22.5, 6 degrees of freedom, p = 0.001

*Group 3 excludes one woman with an inadequate specimen.

Results

The study population was predominantly Black (63.5 percent); the median age was 30 years (range 16–66). Neither age nor race was associated with environmental tobacco smoke exposure.

A total of 32 women reported exposure to environmental tobacco smoke in the home (group 1), 42 reported exposure only outside the home (group 2), and 71 were unexposed (group 3). In group 1, 24 reported one active smoker in the home, five reported two active smokers, and three reported three or more active smokers in the home. Seven in group 1 recalled additional exposure to tobacco smoke outside the home.

Nicotine values ranged from below the limit of detection (<0.2 ng/ml) to 8.2 ng/ml. Nicotine levels tended to be highest among women in group 1 (exposed in the home), intermediate in group 2 (exposed only outside the home), and lowest in group 3 (not exposed). The median values for the three groups were: group 1, 0.8 ng/ml (range, <0.2–8.2), group 2, 0.4 ng/ml (range <0.2–5.2), and group 3, 0.2 ng/ml (range <0.2–3.8).

For grouped analysis, the nicotine levels were divided into approximate quartiles as shown in Table 1. The association of recalled environmental tobacco smoke exposure in the past 24 hours and detectable nicotine in cervical lavages was highly significant (p = 0.001).

Among the 38 women with exposure at home in the past 24 hours, there was no association observed between nicotine levels and the number of smokers to whom the women had been exposed, the usual smoking intensity of those active smokers, or the number of hours since last exposure. Moreover, for women exposed to smoke in the home, additional exposure outside the home was not related to nicotine level. Cigarette smoke accounted for virtually all of the exposure at home. Among women exposed only outside the home, there was no relationship observed between time since last exposure to environmental tobacco smoke and nicotine level.

Discussion

We observed a significant association between self-reported exposure to environmental tobacco smoke within the previous 24 hours and nicotine levels in cervical lavages from a group of 145 nonsmoking women. Exposure in the home resulted in the highest nicotine levels observed; however, women exposed only outside the home also had elevated levels of nicotine compared to those not exposed.

The biological significance of cervical nicotine levels resulting from passive exposure to tobacco smoke is not known. The levels of nicotine observed in nonsmokers most heavily exposed in our population were on average much lower than those seen in cervical lavages taken from active smokers. We found the median nicotine level in nonsmoking women exposed to environmental tobacco smoke at home to be 0.8 ng/ml (mean 1.1), ranging up to 8.2 ng/ml. We were unable to relate nicotine levels to more subtle distinctions, such as the intensity of home exposure. In contrast, using similar specimen collection and analytic methods, we observed a median value in 31 active smokers of 11.8 ng/ml (mean 34.3, range 2.8–383.4, unpublished data) and were able to correlate increasing intensity of active smoking with increasing cervical nicotine levels (Spearman's r = 0.46, p = 0.009). It is difficult to reconcile the relatively low levels of nicotine that we observed in passive smokers with the large magnitude of the relative risks reported by Slattery, *et al*, who found a risk from passive smoking similar to that of actively smoking women.[8]

It is remarkable, nonetheless, that even a relatively crude exposure categorization provided by questionnaire responses revealed a clear, albeit small, elevation of nicotine levels in the cervical fluid of passive smokers. This supports the idea that even low-level exposure to tobacco smoke in the environment may result in systemic effects, and suggests that passive smoking should be evaluated further as a risk factor for cervical disease. ☐

Ascertainment of Maternal Deaths in New York City

Machelle H. Allen, MD, Wendy Chavkin, MD, MPH, and Joani Marinoff, PA

ABSTRACT

Maternal deaths in New York City are defined as deaths from any cause in a woman while pregnant or within six months of pregnancy termination. Pilot studies seeking to improve maternal death ascertainment found that selected medical examiner reports contributed an additional 10.5 percent of the total maternal deaths, vital statistics review contributed 6.3 percent, linkage of death tapes of women of reproductive age to live birth and fetal death tapes contributed 1.0 percent. Medical examiner cases should be incorporated into surveillance data for accurate ascertainment of pregnancy associated deaths. (*Am J Public Health* 1991;81:380–382)

Introduction

Maternal mortality, like infant mortality, serves as a sensitive indicator of the level of health and health care in a community. Speckhard, *et al*,[1] reviewed death certificates and medical records in Puerto Rico and found that the maternal mortality rate was increased by a factor of four in 1979. Starzyk, *et al*,[2] increased the ascertainment of maternal deaths in Washington state by 68 percent through linkage of birth and fetal death files with death certificates for all reproductive-aged women. In Georgia, an additional 27 percent of maternal deaths were identified via a similar vital record linkage system.[3] A conservative pooled estimate of the degree to which maternal deaths are underreported in the United States is by a factor of one-third.

In an effort to verify the efficacy of New York City's present ascertainment methods, which relies upon manual review of all death certificates and clinical records, we undertook three pilot studies to augment routine surveillance.

Methods

Routine Surveillance in New York City

New York City is one of 14 areas in the United States that includes a specific question, item #29 on the death certificate, to identify a pregnancy-associated death (Figure 1). The front of the New York City death certificate also lists coded items: ICD Code, Operative Code, Conditions of Interest Code. If pregnancy is mentioned anywhere on the death certificate, it should be reflected in one or more of the above codes. Routine surveillance relies upon manual review of all death certificates. If an associated pregnancy is indicated on the death certificate, hospital records and autopsy reports are requested and reviewed by an obstetrician. In New York City a maternal death is defined as the death of any woman dying of any cause while pregnant or within six months of termination of a pregnancy.

Death Certificate Review

All death certificates of women aged 10–49 who had died 1983–84 were manually reviewed in order to identify those deaths whose immediate cause was *not* coded in the ICD 630-676 range (complication of pregnancy, delivery or puerperium) but for which the coded items indicated association with pregnancy. All previously unidentified maternal deaths were verified by reviewing the hospital charts and autopsy reports. Additionally, the death certificates of previously reported maternal death cases were reviewed to assess whether all four items related to pregnancy had been completed. This review focused solely on the operative code and the conditions of interest code. It did not investigate those deaths where the ICD code might indicate a medical complication of pregnancy. This issue was addressed by reviewing selected medical examiners reports as will be described subsequently.

Linkage

The New York State Department of Health linked fetal death files and live birth files from 1983 and 1984 with death files of all New York City resident females ages 10–49 for these same years. Linkage was based on mother's last name, infant's last name or mother's first name being the same on both maternal and infant documents. All potential matches were verified for decedent's maternal status by the authors' review of available hospital charts and autopsy reports.

Medical Examiner Report Review

In New York City, there are approximately 3,000 autopsies performed annu-

ally on reproductive aged women by the Medical Examiner. Selected autopsies from 1983–84 were reviewed. A cause of death considered on clinical grounds to have a high probability of being a medical complication of pregnancy (Table 1) as well as drug-related deaths, homicides, and suicides were selected for review. Available hospital charts were subsequently reviewed to confirm whether or not there had been a recent pregnancy.

Results

A summary of maternal deaths identified by the three pilot methods is presented in Table 2. Six additional maternal deaths were found with only one of the coded items as the indicator of a pregnancy (i.e. solely the ICD, operative or condition of interest code reflected a concurrent pregnancy). Review of verified maternal deaths disclosed that Item #29 had not been completed in 40 percent of these cases. When death tapes of women of reproductive age range were matched with live birth and fetal death tapes, five possible matches were identified. However, review of the hospital charts and autopsy reports revealed only one of these women to have had a recent pregnancy. The results of reviewing the medical examiner's reports are presented in Table 3. These reviews yielded 10 additional pregnancy-related deaths, without any overlap with the other methods.

Adjustment of the maternal mortality rates* to reflect these findings involved a 16.6 percent rate increase in 1983, from 40.8 to 51.6/100,000 live births, and a 33 percent rate increase in 1984, from 24.1 to 32.6/100,000 live births. (A retrospective review of maternal mortality rates for New York City through 1987 reveals that the low rate in 1984 represents an unexplained variance, not a trend.)

Discussion

Review of medical examiner reports proved to be the most useful approach to increasing the ascertainment of maternal deaths in New York City. Routine surveillance identified 82.1 percent of the 95 maternal deaths in 1983 and 1984; review of medical examiner reports contributed 10.5 percent; death certificate review contributed an additional 6.3 percent, linkage contributed 1.0 percent. Unlike Puerto Rico and Washington, ascertainment in New York City was not enhanced by the linkage system. This may reflect the population's high mobility and the alleged use of false names and addresses. A surveillance system utilizing linkage methods will not pick up those deaths associated with therapeutic abortions and ectopic pregnancies since fetal death certificates are not filed in these situations.

Both obstetrical practice and the risk profile of pregnant women have changed over the years. The additional cases identified by these pilot studies reveal some of the impact substance abuse and violence is having on pregnant women and new mothers. Elsewhere we have described human immunodeficiency virus (HIV) related maternal deaths in New York City not detected by routine surveillance.[4]

The results of these pilot studies suggest implementation of a system whereby the medical examiner, or hospital-based pathologist, notifies the maternal mortality surveillance team whenever evidence of a current or recent pregnancy is identified. Physicians filing death certificates need to be reminded to inquire about preg-

---

*This rate is not a true rate but rather a *ratio* of deaths per 100,000 live births, i.e. the numerator describes something different than the denominator.

nancy history in all women in the reproductive age range and to complete certificates thoroughly.

As this nation has not met the Surgeon General's 1990 goals of no more than five maternal deaths/100,000 live births for any ethnic or geographic group,[5] it is an urgent matter to design preventive strategies. In order to do so effectively, it is imperative to ascertain all cases so as to accurately delineate the risk factors and causes of pregnancy-associated death. It is important to note that the New York City maternal death definition and surveillance is not universal. If a national surveillance system is to function effectively all registration areas need to utilize the same definitions as well as procedures. ☐

Acknowledgments

We thank Jean Lee and Louise Berenson of the New York City Department of Health Bureau of Biostatistics, Vito LoGrillo of the New York State Department of Health, and the Medical Examiner's Office of the City of New York. In addition, we would like to thank Drs. Hani Atrash, Andrew Friede, and Roger Rochat of the Centers for Disease Control for assistance in developing these programs.

This work was done without grant support. The findings in this paper were presented at the American Public Health Association annual meeting October 1987.

Oral Public Health Programs for the Elderly: 1989

Michael S. Strayer, DDS, MS

ABSTRACT

Forty-eight of the 50 state dental directors, program managers, or state health officials were interviewed by telephone about the nature of current oral health programs for the elderly and factors that aided or hindered the development of such programs. Oral health programs for the elderly were reported in 30 states (63 percent of respondents). A majority of respondents indicated that a perceived or documented need for oral health programs for the elderly and lobbying by local advocacy groups were instrumental in implementing or planning such programs. (*Am J Public Health* 1991;81:382–384)

Introduction

The "graying of America" is a well-accepted phenomenon, as is its effect on the health care system.[1–5] Preventive oral health services and behaviors offer elderly people potential for enhancing the quality of life through improved chewing ability and reduced pain and infection of dental origin, for example. With a decrease in edentulism rates among succeeding cohorts of elderly[6] and an increase in dental utilization,[7] older adults are likely to seek oral health care in greater numbers than did their parents. The U.S. Surgeon General's Workshop on Health Promotion and Aging noted that additional activities are needed in the areas of oral health education and services for older adults,[8] areas falling within the purview of state and local health agencies.

Out-of-pocket reimbursement is the primary method of payment by older adults for dental care.[9] Of the three principal government health care programs, Medicare provides essentially no dental coverage, and the Veterans Administration limits dental coverage to eligible veterans; although Medicaid provides dental coverage for indigent adults in 43 states, 17 states limit benefits to emergency care, denture services, or both.[10]

At the local level, some agencies have begun to allocate resources to the oral health needs of older adults. Kuthy and Odom reported in 1988 that 16 (of 127) local programs provided clinical services in nursing homes and that oral health education programs were offered by 39 (of

Total	10	11	9

[a] Both clinical care and hearing education.

125) agencies.[11] Evans found that 35 percent of local dental programs reported providing health education programs at senior centers.[12]

At the state level, no recent information is available on oral health programs for older adults. Miller, *et al,* reported that 50 percent of state health agencies had statutory authority to provide dental health services.[13] A 1983 study of state health agencies identified 20 nonclinical geriatric dental initiatives.[14]

The objectives of this project were to determine the extent and nature of current and proposed oral health programs for older adults and to identify factors that had facilitated or hindered the development of such programs.

Methods

A structured interview was designed to address the study objectives and then revised based on several reviews for clarity and content by a panel of professionals in dental public health, geriatric dentistry, research design, and program evaluation.

All known state dental directors or dental program managers were contacted, first by letter and later by telephone, to arrange a mutually convenient time for the interview. In states without a dental director or program manager, another health department administrator was contacted. All data provided by respondents were considered confidential and are reported here in aggregate form only.

Results

A total of 48 state dental directors, managers, or administrators completed interviews, yielding a 96 percent response rate. Although the interviews were subject to the limitations of self-report surveillance, interviews revealed that some level of oral health programming for older adults existed in 30 states (63 percent of respondents).

A variety of oral health education or promotion activities were provided by 25 of the 30 states, primarily in long-term care facilities. Clinical services were provided to the elderly by 16 of the 30 states, with 3 states having direct responsibility and 10 states offering services jointly with a local agency. In the remaining states, clinical services were provided through arrangements with local educational institutions and dental associations or through loans of portable equipment to private dentists. Of the 18 states without programs for older adults, 6 planned to implement health education or prevention programs within 3 years; 2 of the 6 also planned a clinical component.

In the majority of states with programs, two factors that assisted in the development of programs were identified: a perceived or documented need for oral health programs, and a local advocacy group that lobbied for programs. Obtaining funds that could be used for older adult programs assisted program development in most of the states planning programs.

Low state priority for providing oral health services to older adults and funding restricted to population groups other than older adults were identified by a majority of respondents as hindering the development of older adult programs.

Independent variables including proportion of the state population over age 65, total number of elderly persons in the state, eligibility of elderly to participate in the state Medicaid program, and size of the state dental budget were examined to determine their utility as predictors of a state program. However, none of the independent variables predicted the presence of a state oral health program for the elderly. Table 1 shows the distribution of oral health programs by states in which the elderly population was the same, higher, or lower than the national average of 11 to 12 percent. No evident relation of program and population can be seen.

Discussion

Although changes in dental health care priorities seem inevitable, they must be preceded by careful needs assessment, so that resources are allocated to the most compelling problem areas. To understand the scope of such problems, the needs assessment process should include development of a data base on the dental needs of older adults, both perceived and observed; identification of dental services available to or needed by older adults; and identification of the ranking of dental care on a list of health priorities.

Oral health programs for older adults that were reported to be more comprehensive shared the following three characteristics: a commitment by the state agency to provide oral health programs for older adults, active interest by organized dentistry, and some form of linkage with the local aging network (such as local Area Agencies on Aging or a state Department of Aging). The scope and magnitude of the physical, psychological, and socioeconomic problems encountered by the elderly in obtaining and paying for oral health care make the support of this triad vital to the successful development and implementation of oral health programs for older adults.

A majority of respondents perceived that lobbying by local advocacy groups had assisted in implementing oral health programs and that the lack of such an organized group was a hindrance. This area is one where appropriate assistance must be offered; access to dental consultants with gerontologic training could be extremely helpful to state agencies in their work with diverse advocacy groups. Dental public health can have a significant role in improving the quality of life for the elderly by using the health promotion and prevention skills that improved the oral health of younger populations. ☐

Effect of Pregnancy during TMI Crisis on Mothers' Mental Health and Their Child's Development

Peter S. Houts, PhD, George K. Tokuhata, DrPH, PhD, Jane Bratz, BS, Mary J. Bartholomew, MS, and Kirby W. Sheffer, MS

ABSTRACT

Five years after the Three Mile Island nuclear accident, the mental health of women who had been pregnant and living within 10 miles of Three Mile Island at the time of the accident was similar to that of women from the same area who became pregnant after the accident. Ratings of the development of the two groups of children when they were 5 years old were also similar. However, women who were pregnant during the crisis and had been "extremely disturbed" about their pregnancies rated their children's health as poorer than did the women who were pregnant later. (*Am J Public Health* 1991; 81:384–386)

Introduction

A review of published research on the psychological and social effects of the Three Mile Island (TMI) accident showed that women living near the facility who were pregnant or had young children were among those who experienced the greatest psychological distress following the accident.[1] A study conducted by the Pennsylvania Department of Health showed little biological effect of the accident on women who were pregnant during the crisis and on their children.[2]

Five years after the accident, the Pennsylvania Department of Health conducted follow-up studies to assess long-term physical and psychological impacts of the TMI crisis on these same women and children. We report here interviews with the mothers concerning their perceptions of their children's health and development and their own mental health.

Method

The study and control cohorts consisted of 7,433 women who gave birth within 2 years of the TMI accident and lived in communities within 10 miles of the nuclear facility at the time of the births. A 50 percent random sample of each of these cohorts was selected: 1,880 mothers who gave birth within 12 months of the TMI accident; and 1,850 mothers who gave birth from 13 to 24 months after the accident. The latter group served as controls. Mothers who had moved out of the area since their children's births, as well as mothers who still lived in the vicinity of TMI, were interviewed. A 97 percent response rate was achieved for each sample,

TABLE 1—Multiple Regression Analyses Comparing Ratings of Mothers' and Children's Health by Mothers in the Study and Control Groups (N = 2,585)

Dependent Variables	Regression Coefficients for Study-Control Comparisons[a]	Standard Error
Ratings of child's health (high score = poor health)	.0438	.0185
Number of child's visits to physician in past year	.0536	.0317
Developmental profile (high score = poor development)	.0310	.0685
Preschool behavior scale (high score = emotional problems)	.0241	.0211
Ratings of mother's health (high score = poor health)	−.0000	.0174
Mother's depression score	.0151	.0095
Mother's anxiety score	.0147	.0088

Notes: Covariants are listed in text. N varies slightly with number of missing values for each dependent variable. [a]Control group = 0, study group = 1.

TABLE 2—Analyses of Covariance of Mothers' Mean Ratings of Their Children's Overall Health by Timing of Pregnancy and Disturbance about Pregnancy

Disturbance about Pregnancy	Pregnant During Crisis	Pregnant After Crisis	P value of Difference
Extremely disturbed	2.17 (N = 327)	1.95 (N = 87)	.0236
Somewhat disturbed	1.88 (N = 667)	1.94 (N = 478)	.3358
Not disturbed	1.69 (N = 388)	1.71 (N = 638)	.7284

Note: Health was rated 1, excellent; 2, very good; 3, good; 4, fair; or 5, poor. Covariants are listed in text.

yielding 1,833 pairs of mothers and children in the study sample and 1,808 pairs in the control sample.

The analyses reported here involved women who were pregnant at the time of the accident, i.e., those who gave birth during the 9 months after the accident (study group), and those who gave birth during the corresponding 9 months a year later (control group). The study group was interviewed in 1985 when the index children were 5 years old, and the members of control group were interviewed in 1986 when their children were also 5 years old.

The dependent variables analyzed were the number of physician visits,[3] the developmental profile for 5-year-old children,[4] the preschool behavior scores suggestive of emotional problems,[5,6] the mothers' anxiety and depression scores,[7,8] and the mothers' overall ratings of their children's and their own health.

Results

We fitted multiple regression models with terms for study versus control group, month of child's birth, child's sex, child's birth order, mother's marital status, time mother spends caring for child, mother's education, mother's employment status, mother's race, mother's age, household size, and distance of home from TMI at the time of the crisis. Dependent variables were log transformed to adjust for skewness.

Table 1 shows that all but one coefficient (mother's health) are in the direction suggesting poorer status for the study group. Only one coefficient, however, mothers' overall ratings of their children's health was statistically significant. Women who gave birth within 9 months of the accident gave their children's health poorer mean ratings than women who gave birth in the same months a year later.

Examination of the distribution of these general health ratings showed that the difference in the two groups was largely in the percentage of mothers who rated their children's health as "excellent"; that percentage was 7 percent lower among the study mothers than among controls. We also examined interactions among the study and control groups' ratings and mothers' age, birth order of the child, and mothers' education while controlling for the same 11 covariants. No interactions were statistically significant.

Mothers were grouped based on how disturbed they said they had been about their pregnancies when they were interviewed 5 years earlier, shortly after their children's births (Table 2). The poorer health ratings were primarily among mothers who had been "extremely disturbed" about their pregnancies. The statistic for this interaction effect had a probability of .0635. The difference between the two groups was significant only for the "extremely disturbed" group.

Discussion

The interview data reported here are primarily subjective and indicate how the experience of being pregnant during the TMI crisis affected the mothers' views of their children and themselves. Although the findings showed a poorer status for women who were pregnant during the crisis, the differences between this group and the controls were small. The only notable difference was in the smaller proportion of study group mothers who rated their children's health as "excellent." Small but statistically insignificant differences between women who were pregnant during the crisis and women who became pregnant afterward were found for long-term anxiety, long-term depression, ratings of the children's development, and reports of children's physician visits.

Women who were pregnant during the crisis and who were also "extremely disturbed" about their pregnancies tended to rate their children as less healthy. This pattern is similar to that reported by Roht, *et al*, who found that people living near toxic waste sites were more likely to report health problems if they believed that the sites could affect their health.[9] Roht, *et al*, interpreted their findings as an example of response bias induced by the expectations of the respondents.

The present findings can be interpreted similarly: that is, the mothers of children born within 9 months of the TMI accident, who were "extremely disturbed" because of possible long-term effects of radiation released during the accident, may have paid special attention to their children's health problems, resulting in the general impression that their children were less healthy. Whether these children were less healthy than controls will be investigated further in a medical record review study now in progress. ☐

Acknowledgments

This research was supported by the Pennsylvania Department of Health, Division of Epidemiology Research. An earlier version of this paper was presented at the American Public Health Association Meeting in November 1988. The authors appreciate the help of Dr. Arthur Hartz in analyzing these data.

Using a State Cancer Registry to Increase Screening Behaviors of Sisters and Daughters of Breast Cancer Patients

Peter S. Houts, PhD, Sandra L. Wojtkowiak, BSN, Mary A. Simmonds, MD, Gene B. Weinberg, DrPH, and Daniel F. Heitjan, PhD

ABSTRACT

The Pennsylvania Cancer Registry was used to contact breast cancer patients and, through them, their adult sisters and daughters. The sisters and daughters were counseled concerning their higher than average risks for breast cancer and their need for mammography and breast self-examination. Results showed a 9 percent increase in mammography and a 10 percent increase in breast self-examination rates for the counseled over control group. Costs were $49 per counseled sister or daughter indicating a need to increase cost effectiveness before implementation is practical. (*Am J Public Health* 1990; 81:386–388)

Introduction

Cancer registries have contributed to the treatment and prevention of cancer by making it possible to study the distribution of the disease, its causes, and the planning of services.[1,2] Women whose mothers or sisters have had breast cancer have two to three times the usual risk for developing breast cancer in their lifetimes.[3] We used the registry to contact breast cancer patients and through them first degree female relatives in order to counsel them about what to do to ensure early diagnosis and treatment of breast cancer, should it be found.

Methods

Potential participants were sisters and daughters of breast cancer patients diagnosed between June 1982 and June 1984 and living in eight counties in central Pennsylvania. Names of all breast cancer patients from four counties were obtained from the Pennsylvania Cancer Registry at the beginning of the study and randomly assigned to three groups where sisters and daughters were to be counseled in years 1, 2 and 3, respectively, of the project. At the end of the first year, four additional counties were added to the study and randomly assigned to the years 2 and 3 groups. At the end of 21 months, the knowledge, attitudes and behavior of sisters and daughters of breast cancer patients in all three groups were assessed using telephone interviews. Those who had received counseling in the first 21 months were "experimental," while those yet to be counseled were controls. This design controlled for the effects of media attention and public education programs that occurred during the first 21 months of the study.

Permission to contact the patients was obtained from the physicians listed on the cancer registry forms. When permis-

TABLE 1—Characteristics of Study Populations

Patients	Experimental	Control
Total number selected[a]	611	395
MD permission given	431 (71%)	221 (56%)
Pts who agreed to participate	302 (70%)	165 (75%)
Number with eligible sisters or daughters[b]	160	111
Mean patient age[b]	62	61
Stage of disease at diagnosis[b]		
Stage I	4%	4%
Stage II	70%	53%
Stage III	25%	40%
Stage IV	1%	3%
Year of diagnosis[b]		
1982	27%	14%
1983	56%	48%
1984	17%	38%
Sisters and Daughters		
Total number participating	370	242
daughters	46%	48%
sisters	54%	52%
Mean age	48	46
Education		
Less than high school	26%	24%
High school graduate	45%	48%
Post high school	29%	28%

a) Excludes patients who died before evaluation interviews or were living outside of Pennsylvania.

b) Excludes patients without sisters or daughters, or where sisters and daughters were less than 18 years of age or were living outside Pennsylvania.

TABLE 2—Sisters' and Daughters' Knowledge and Behaviors Concerning Breast Cancer[a]

	Experimental Group	Control Group	Estimated Treatment Effect (95% CI)[e]
Information[b]			
Mean percent of correct answers on general information about breast cancer	71%	65%	6.83% (4.51, 9.15)
Mean percent of correct answers on signs of breast cancer	30%	24%	6.75% (4.61, 8.90)
Breast Self-examination[b]			
Confidence in ability to do BSE (0 = not at all, 3 = very)	2.23	2.04	.20 (.07, .32)
			Relative Odds (95% CI)[f]
Percent doing BSE monthly or bimonthly	49%	39%	1.53 (1.08, 2.17)
Mammography[c]			
Percent ever having a mammogram	57%	52%	1.36 (0.91, 2.03)
Percent who had a mammogram since receiving education[d]	39%	30%	1.57 (1.03, 2.40)

a) Controlling for the index patient's stage at diagnosis and year of diagnosis and the respondent's age, education and whether she was a sister or daughter.

b) Experimental group N = 369, Control group N = 242.

c) Only sisters and daughters ages 35 and older. Experimental group N = 269, control group N = 185.

d) Experimental group women were asked if they had a mammogram since their telephone education and the control group was asked the date of their most recent mammogram. Persons in the control group were scored positively if they had a mammogram in the past 21 months, which was when experimental group education occurred.

e) Continuous outcome: additional effect of treatment on mean response when all other factors are held constant.

f) Dichotomous outcome: relative odds for treated versus control respondents when all other factors are held constant.

sion was given, patients were contacted and asked for access to their sisters and adult daughters living in Pennsylvania who were then reached and counseled by telephone. Counseling consisted of asking questions about their knowledge, attitudes, and behaviors related to breast cancer and, where responses were not consistent with American Cancer Society (ACS) guidelines, explaining and discussing the reasons for the guidelines. The counselors urged the sisters and daughters to follow ACS guidelines because of their risks for future breast cancer and the excellent prognosis when cancer is discovered at an early stage.

All sisters and daughters were invited to attend education sessions held throughout the eight-county study area and were encouraged to come in family groups. The education sessions included explanations of breast cancer risks, the importance of breast self-examinations (BSE) and mammography as well as opportunities to practice BSE on model breasts and on themselves.

Results

Characteristics of the experimental and control groups are shown in Table 1. The control group had a lower physician permission rate, fewer early stage diagnoses, and more recent diagnoses. One-third of experimental group women attended the voluntary teaching sessions in their communities.

Table 2 reports estimated effects of the experimental treatment on general knowledge of breast cancer, breast self-examination, and mammography. Multiple linear regression was used to make comparisons between the groups based on continuous outcomes, and multiple logistic regression was used to make comparisons based on dichotomous outcomes. All analyses adjust for index patient's stage at diagnosis and year of diagnosis and the respondent's age, education, and whether she was a sister or a daughter. Treatment effects were parameterized as the additional effect of treatment on the mean response for continuous outcomes, and as the relative odds for treated versus control for dichotomous outcomes. As the table shows, all comparisons favored the treatment group, although the effects were not large.

We also investigated a number of possible interactions including: whether those who attended the group sessions showed a greater change in screening behaviors than those who did not attend; whether sisters responded differently to the program than daughters; whether higher socioeconomic status women responded differently than lower socioeconomic status women; whether younger women responded differently than older women; and whether the index patient's stage of disease at diagnosis was related to the program's impact. None of these variables interacted significantly with the experimental/control variable in their effects on the sisters' and daughters' breast self-examination, ever having a mammogram, or having a mammogram since receiving education. We also investigated whether the eight counties were significantly different on any of the outcome measures. They were not.

Cost estimates, based on hours spent by project personnel, were $49 per sister or daughter counseled. Twenty-five percent of these costs were expended in obtaining physician permissions, 50 percent in obtaining patient permissions and counseling relatives, and 25 percent was for supervision and secretarial support.

Discussion

The medical and demographic differences between the experimental and control groups may be the result of when subjects were recruited. Since the control group was recruited last, they had the greatest gap between diagnosis and recruitment which may have contributed to their lower physician permission rate and lower participation among patients with early stage at diagnosis.

The findings indicate that the program did affect participants' knowledge, attitudes and behaviors, although the impact on behavior was generally modest. Moreover, only half of the eligible sisters and daughters were counseled due to high physician (29 percent) and ~~patient (30~~ percent) refusal rates. At the time of the evaluation interviews, 43 percent of counseled sisters and daughters over age 35 had never had a mammogram. Similar findings have been reported with other groups at high risk for cancer.[4,5]

The control group mammography rate of 52 percent is also of interest because it is about 10 percent higher than has been reported for the population as a whole[6,*] suggesting that a substantial number of these high-risk women had already taken action to deal with their increased risks. This may have limited the potential impact of the program.

If this program were implemented statewide in Pennsylvania, assuming the same physician and patient refusal rates, the cost would be approximately $227,000 yearly. If, as in this study, there was a 9 percent increase in mammogram rates and, assuming a 1 percent yield of cancers detected (double the usual rate because of working with a high risk population), four cancers would be discovered earlier than otherwise at a cost of $56,963 per diagnosis. The real costs may be lower than these estimates since the excess in mammography rates could be assumed to occur in subsequent years as well. Furthermore, costs of recruiting physicians might also be lower in future years because physicians' increased familiarity and experience with the program might result in more responses to first requests, thereby requiring less follow-up effort. An alternative approach could be to ask physicians to voluntarily refer high-risk patients to the education program. This would reduce recruitment costs and possibly increase patient participation, but would make the program more dependent on physician cooperation. We conclude that it is feasible to use a state cancer registry to contact and counsel first degree relatives of cancer patients, but that additional work is needed to increase the program's cost effectiveness. ☐

Acknowledgments

We would like to acknowledge the assistance of the following persons in carrying out this research: Dr. Harold Harvey and Dr. Richard Landis for their help in data analysis and interpretation, Sandi Ezrine for help in data collection, and Thelma Wallace and Bonnie Ference, RN for help in conducting the education program.

This research was supported by the Pennsylvania Cancer Plan of the Pennsylvania Department of Health. An earlier version of this paper was presented at the American Society of Clinical Oncology meeting, May 1988.

Cost-Effectiveness of Alpha-1 Antitrypsin Replacement Therapy in Treatment of Congenital Chronic Obstructive Pulmonary Disease

6T

Joel W. Hay, PhD, and Eugene D. Robin, MD

ABSTRACT

Background: Alpha$_1$-antitrypsin (AAT) replacement therapy is an expensive intervention ($20,000–$30,000 per patient annually) which may slow or arrest the progression of chronic obstructive pulmonary disease (COPD) in AAT-deficient patients. While FDA-approved, therapy efficacy is unknown. The costs and benefits of AAT replacement therapy were evaluated for patients with congenital COPD.

Methods: Epidemiological and disease cost data were taken from published sources. A discrete-time model of disease stage probability transition was developed to calculate the present-value expected cost of disease treatment, under a range of possible therapy efficacy and other parameter values.

Results: At an efficacy of 70 percent, the cost per life year saved with AAT replacement therapy would be between $28,000 and $72,000 (1990 US dollars), depending on patient age, sex, and smoking status. At 30 percent efficacy, the cost per life year saved range would be between $50,000 and $128,000. A controlled efficacy study would cost $53 million or less, if the true efficacy were 50 percent or better.

Conclusions: With efficacy of 30 percent or higher, therapy cost-effectiveness would be comparable to other widely used medical interventions. The economic assessment methodology was used to evaluate both the therapeutic innovation and the value of additional clinical research. (*Am J Public Health* 1991; 81:427–433)

Introduction

More than 10 million Americans are afflicted with chronic obstructive pulmonary disease (COPD). It has been estimated that roughly 1 percent of this condition is caused by congenital alpha$_1$-antitrypsin (AAT) deficiency.[1] AAT is a human protease inhibitor which acts in the interstitial lung tissues to prevent damage caused by neutrophil elastase. In addition to COPD, AAT deficiency leads to other clinically significant disorders, including hepatic complications in about 10 percent of patients.[2,3]

In a prospective Swedish study, 8 percent of 183 AAT-deficient eight-year-old children had asthma or bronchitis in the previous year.[4] The mean age for onset of dyspnea, presumably related to COPD itself, was 40 to 45 years in patients with AAT deficiency. The mean life expectancy was 50 to 65 years. Smokers with AAT deficiency experienced a more rapid clinical course, with age at onset of symptoms and age at death advancing by more than a decade relative to nonsmokers.[3]

Human alpha$_1$-proteinase inhibitor (Prolastin) has been approved by the Food and Drug Administration (FDA) for replacement therapy in emphysema patients with congenital AAT-deficiency. Because of the small potential market, it has been granted "orphan drug" status. AAT replacement therapy has been shown to improve the levels of AAT in serum and epithelial tissue.[5] The clinical efficacy of AAT replacement therapy in slowing congenital COPD progression is not yet known.

Unusual policy issues are raised in examining the efficacy and cost-effectiveness of this therapy, with its small number of potential beneficiaries. Because a prospective randomized clinical trial to determine outcome efficacy could cost over $1 billion (see below), health care providers and patients must use other means to decide whether or not to make use of a medication of high cost and unknown benefit. This lack of detailed data on therapeutic risk and benefit arises often, since many forms of medical therapy are used in the absence of controlled clinical trials.

Despite the uncertainties regarding therapeutic outcomes, new immunoassays for AAT-deficiency blood screening are under development (E. Silverman, personal communication, January 1990). Several public health agencies are examining population screening, including the state of Oregon, which is considering adding AAT-deficiency screening to its list of required blood tests for newborns (S. Buist, personal communication, May 1990).

No prior studies have specifically addressed the medical costs associated with AAT deficiency. Previous studies have found the medical and economic costs of COPD to be substantial,[5,7] Oster et al. reported the average medical costs per patient year to range from $587 to $6,238 (1990 dollars) for COPD patients, depending on the number of years after onset of symptoms.[7] In a prospective study of the medical costs for treatment of COPD, Strauss *et al*[8] and Bergner *et al*[9] reported costs averaging $14,647 per year (1990 dollars). The Bergner *et al* study sample was limited to homebound patients with both a

*Source: Adapted from Larsson[3]

COPD diagnosis and Forced Expiratory Volume (FEV_1) scores below 60 percent of normal, a severely impaired group.

Using a societal perspective to measure costs and benefits, we applied available data on congenital COPD incidence, prevalence, patient survival, and costs of COPD medical treatment to cost-effectiveness evaluation of therapy. By examining the cost-effectiveness of AAT replacement therapy under alternative efficacy assumptions, we consider whether determination of therapeutic efficacy would itself be cost-justified. Possible strategies for population screening of congenital AAT-deficiency are also briefly considered.

Methods

We estimated costs per life-year saved (CLYS) for homozygous (PiZ) AAT-deficient individuals: the ratio of the change in expected net COPD medical cost resulting from AAT replacement therapy relative to the change in years of life saved through the intervention (see Appendix).[10–12] Future costs and benefits were discounted to current age using a discount rate of 5 percent.[11–14]

The best available evidence on the natural history of disease in AAT-deficient individuals was reported by Larsson, based on 1 to 14-year follow-up data for 246 Swedish adults with PiZ AAT-deficiency.[3] Column one of Table 1 adapts Larsson's survival data to the adult US population using 1986 US vital statistics. Early estimates of the median survival subsequent to diagnosis of COPD were consistently around five years among subjects with an initial FEV_1 close to 1.0 liter.[15,16] A more recent study by Burrows *et al* shows longer overall survival, but with substantial differences across COPD subcategories.[17] In atopic subjects or nonsmokers with known asthma, the ten-year mortality rate (not age adjusted) was 15 percent, while for smokers with an emphysematous form of COPD, the ten-year mortality rate was 60 percent. Since the mean age in the Burrows *et al* study population was 63, the ten-year survival for the milder forms of COPD was presumably little different from that for non-COPD individuals. The eight-year median survival for emphysematous smokers reported by Burrows *et al* probably more closely matches the prognosis for AAT-deficient patients after COPD diagnosis. While long-term use of therapy might improve or impair the quality of life, we use change in survival as the prime criterion for therapeutic efficacy and outcome assessment.

COPD Medical Care Costs

Several studies show that AAT-deficient individuals tend to develop relatively severe forms of COPD.[1–3] We used the Bergner *et al* and Strauss *et al* medical care cost estimates.[8,9] In their multivariate estimates, annual costs of care did not change with physician specialty, type of hospital (federal or community), insurance coverage, age, sex, income, entry FEV_1 score, length of study participation, or death of patient.[8,9]

The Bergner *et al* and Strauss *et al* study subject inclusion criteria, patient survival, and patient demographic characteristics matched those of the Burrows *et al* study fairly closely, suggesting that a six- to 10-year median COPD patient survival with annual medical costs of $12,000 to $16,000 (1990 dollars) would characterize the course of COPD after diagnosis in AAT-deficient individuals. Conservatively, since no estimates are reported in the recent COPD cost studies, we ignored diagnostic and treatment costs associated with respiratory disease prior to development of FEV_1 values below 65 percent of normal, or with other symptoms outside the Burrows *et al* emphysematous subject category definition. As shown below, this downward bias on the medical cost estimates would have little impact on the CLYS estimates.

Table 1, column two shows the present value of lifetime expected COPD medical care costs, estimated by attributing average excess medical costs per year over the eight-year median survival period prior to death for the fraction of excess deaths due to COPD in each age-, sex-, and smoking-adjusted five-year interval for PiZ cohorts (see Appendix).

AAT Replacement Therapy Intervention

Human alpha$_1$-proteinase inhibitor (Prolastin) is prepared from human plasma screened for hepatitis B and human immunodeficiency virus (HIV) antibodies and heat-treated for at least 10 hours. Hepatitis B vaccine is recommended for all

TABLE 2—Cost per Year of Life Saved by AAT-Deficiency Replacement Therapy at Patient Age 40 ($1,000s)

Outcome Efficacy	PiZ Males		PiZ Females	
	Smoking	Nonsmoking	Smoking	Nonsmoking
10%	$107	$352	$107	$214
30%	$ 50	$128	$ 49	$ 83
50%	$ 38	$ 83	$ 38	$ 56
70%	$ 33	$ 64	$ 32	$ 45
90%	$ 29	$ 53	$ 28	$ 38

recipients, and hepatitis B immune globulin is recommended for recipients who have not yet developed adequate antibody titers.

Prolastin is infused intravenously once per week at a dosage of 60 mg/kg. The current medication cost is $0.10 per mg, or $20,000 per year for a 64 kg adult.[18] The safety record for Prolastin has been described as excellent to date.[19] We assumed average annual costs would be $30,000 to include pharmacy markup, physician monitoring, intravenous infusion, and treatment of side effects. We also assumed that, once initiated, therapy would be maintained throughout the patient's life.

We found no data relating Prolastin in treatment of COPD to improvement in patient outcome. Wewers *et al*, in a study of the safety and biochemical efficacy of Prolastin, provided 507 infusions to 21 PiZ homozygous AAT-deficient patients.[5] They found fourfold increases in AAT serum and epithelial lining fluid levels and doubling in anti-neutrophil elastase capacities subsequent to infusion, but these changes may not reflect improved patient outcome.

AAT-deficiency also produces liver disease, hemorrhagic disorders, pancreatic fibrosis, and other less frequent symptoms.[2,3] Prolastin has shown efficacy in treatment of panniculitis in PiZ patients.[20] However, no efficacy has been suggested for Prolastin for other non-COPD disorders associated with congenital AAT deficiency.[2]

It is not known whether congenital COPD can be fully prevented, somewhat slowed, or merely delayed, so it would be inappropriate to assign a specific value for the outcome efficacy of AAT replacement therapy in treatment of congenital COPD and/or other clinical disorders caused by congenital AAT deficiency. Instead, we have opted to define a hypothetical "outcome efficacy" in terms of the percentage of potential normal survival (age-, sex-, and smoking-status-adjusted) that could be salvaged through therapeutic intervention, and to show the cost-effectiveness of AAT replacement therapy at different "outcome efficacy" values ranging from 0 to 100 percent. That is to say, for each five-year age interval, we define the "outcome efficacy" as x percent if the AAT-deficient individual's probability of survival during that period has increased by x percent relative to a normal (non-AAT-deficient) individual (see Appendix). We do not attempt to detail the specific clinical pathways whereby these hypothetical survival benefits would be achieved.

Results

Table 1, column three shows the net present value of lifetime expected AAT replacement therapy costs in thousands of dollars assuming an "outcome efficacy" of 70 percent. Lifetime therapy costs can only be estimated contingent on efficacy level, since lower efficacy levels will reduce the patient's survival probabilities and thus lower the lifetime expected cost of therapy. The figures in column three also net out the savings in medical treatment of COPD due to reduced probability of disease. Column four shows the change in life expectancy associated with a 70 percent "outcome efficacy" for each age-, sex-, and smoking-status-adjusted cohort. Column five provides CLYS estimates for each adjusted cohort under the assumptions described above, including 70 percent "outcome efficacy," 5 percent time discount rate, eight-year median survival from time of COPD diagnosis, $30,000 annual cost of AAT replacement therapy, $14,647 annual medical cost for treatment of COPD, and a healthiness weight of 75 percent (of normal) applied to average reported days of excess restricted activity (see Appendix). The CLYS values ranged from $27,624 to $71,945; for smoking males and females, most CLYS values were at or below $40,000, while for nonsmoking males and females they were $41,000 to $72,000.

It is a bit puzzling that the CLYS would be as low as $28,000 when the annual AAT treatment cost is $30,000. However, based on the Larsson data, compared with normals, the relative risk of death for PiZ smokers is extremely high, ranging from 27:1 for 35-year-old PiZ male smokers to 4:1 for 60-year-olds. For the individuals at highest risk, after discounting future costs and benefits, and netting out the avoided COPD medical costs (Table 1, column two), at hypothetical "efficacy" levels of 70 percent, $30,000 of therapy buys about a year of additional life expectancy.

To put results shown in Table 1, column five in perspective, they are within the range of such values reported for a number of generally accepted medical interventions. For example, adjusting to 1990 US dollars, Drummond reported that treatment of hypertension in 40-year-old males would cost $30,200 per year of life saved, estrogen therapy for postmenopausal women would cost $42,600, single-vessel coronary bypass would cost $57,400, and hospital hemodialysis would cost $85,400.[10] Kinosian and Eisenberg reported that antihypercholesterolemia therapy would cost between $20,500 and $135,000 per year of life saved, depending on heart disease risk factors.[11]

Table 2 shows the impact of alternative "outcome efficacy" assumptions on AAT replacement therapy CLYS values, holding all other parameters at the same values as in Table 1, column five, for 40-year-old adults. At 10 percent "outcome efficacy" the CLYS estimates exceeded $100,000 but at 90 percent "outcome efficacy" they dropped to less than $30,000 for PiZ smokers. Even if AAT replacement therapy were able to improve congenital COPD survival probabilities by a relatively low 30–50 percent, the values would still be within the range calculated for other frequently used medical interventions, particularly for PiZ smokers.

Sensitivity Analysis

Table 3 shows the effects of 40 percent changes in each key model parameter. The CLYS results are fairly stable. Of the five key model parameters shown, only changes in the annual cost of AAT replacement therapy induced as much as a one-for-one percentage change in CLYS values. Thus, with the exception of assumed "outcome efficacy" (Table 2) and therapy cost, the results were not highly sensitive to underlying modeling assumptions.

TABLE 3—Sensitivity Analysis of Base-Case Model CLYS Values: Effects of ±40 Percent Change in Each Parameter

	PiZ Males (Age 40)		PiZ Females (Age 40)	
	Smoking	Nonsmoking	Smoking	Nonsmoking

90%	0.139	80	$ 12	$ 40,440

Should an Outcome Efficacy Study Be Done?

We can now consider the costs and benefits of undertaking a clinical trial to establish efficacy of AAT replacement therapy. It has been estimated that demonstration of a statistically significant therapeutic efficacy in slowing the decline of lung function would require a clinical trial involving 300–500 patients over a five-year study period.[21] Generally, the value of a randomized controlled clinical trial depends on the prior probability distribution of successful trial outcomes, the size of treatment effect needed to show clinical benefit, and the relative rates of outcome events (e.g., deaths) in treatment and control patients.[22–25] In the case of the already approved AAT therapy, there are penalties associated with not establishing therapeutic efficacy irrespective of the true value. If the true outcome efficacy is very high, many potential beneficiaries may be missing an important medical intervention. If the efficacy is low, then it may be that too many dollars are already being devoted to an expensive but ineffective therapy.

Table 4 considers the design parameters of a randomized controlled trial to evaluate AAT replacement therapy efficacy. Based on the PiZ survival estimates described above, the average five-year mortality probability for a PiZ cohort age 30–60, with equal numbers of men and women and 30 percent smokers would be 18.4 percent. Greater study efficiency would result if the study were targeted to higher risk patients by age, sex, or smoking status, but the generalizability of the findings would then be suspect. For each hypothetical "outcome efficacy," the second and third columns of Table 4 show, respectively, the expected five-year mortality difference and the minimum study sample size needed per study arm to achieve 80 percent power (20 percent risk of false negative results) with a two-sided alpha significance level of .05.[24,26]

Table 4, column four, shows the cost of the study under the assumption that each patient in the AAT therapy arm would require five years of therapy at $30,000 per year. Additional study monitoring, data collection and analysis costs would be trivial relative to these therapy costs. Given that the annual NIH research budget is around $7 billion, less than $3,400 per fatality, study samples needed to detect "outcome efficacy" levels below 30 percent would be prohibitively expensive, particularly since the therapy might partially benefit only 50,000 to 100,000 individuals.

The economic analysis implies that clinical and statistical considerations are not sufficient design criteria in this case. Table 4, column five shows the average CYLS from AAT therapy at each "outcome efficacy" level, assuming that it would be impossible to restrict access to medication by age, sex, or smoking status if the therapy were found to be significantly effective in extending life expectancy. As shown, the "outcome efficacy" of AAT therapy would have to be 50 percent or better to be cost-effective relative to other medical therapies and thus to be economically viable. Detecting economically justifiable therapeutic benefits would thus require smaller sample sizes than would be implied by focusing exclusively on clinical decision criteria. Alternatively, to achieve greater efficiency, the clinical trial could be targeted by age, sex, smoking status, or other risk factors, and if successful, the therapy usage indications could be similarly restricted.

TABLE 5—Projected Costs of Screening for PiZ Emphysema in Various Subpopulations (All Figures in Millions)

	Relevant Adult Population	Cigarette Smokers	Subjects with Established Emphysema	Relatives of Patients with Emphysema	Relatives of Patients with Alpha-1 Antitrypsin Globulin
Estimated Size of Population	100	30	10	20	0.5
Cost of Screening (Dollars)	10,000	3,000	1,000	2,000	50
Cost of Follow-up (Dollars)	1,000	300	100	200	166
Number of False Positives	1	0.3	0.1	0.2	0.005

Congenital COPD Screening Strategies

The availability of a new therapy also raises the issue of the cost-effectiveness of screening to detect early disease and to institute therapy to prevent or retard progression. With rare diseases such as AAT deficiency, the assumed screening rate of false positives has a major impact on the value of screening programs. There are two types of false positive measurements. Technical false positives relate to problems in the performance and interpretation of clinical tests. Biological false positives occur in subjects with a given biochemical or genetic abnormality that is never expressed in frank disease. We assumed that the rate of the former was 1 percent, which is conservative for most tests. We also conservatively chose to ignore biological false positives. However, in a small sample, 25 percent of PiZ homozygotes showed little evidence of COPD.[3] In another study, nonsmoking PiZ homozygotes demonstrated substantial variability in FEV measurements and in COPD prevalence, suggesting a high rate of biological false positives.[1]

We examined some alternative populations that might be screened, estimated false positive rates, and evaluated the screening costs (Table 5). We conservatively ignored the follow-up and treatment costs for false positives. Since only 50,000 to 100,000 individuals in the United States are potentially treatable, some of these screening strategies would add significantly to the cost of intervention, even if Prolastin were highly efficacious. Choice of screening strategies should therefore await more precise efficacy calculations.

Discussion

COPD in congenitally AAT-deficient individuals is a severe, life-threatening illness. AAT replacement therapy leads to promising biochemical improvements in serum and lung-fluid measurements. Our analysis showed that if AAT replacement therapy were able to narrow the age- and sex-adjusted survival probability gap between PiZ and normal individuals by at least 30–50 percent, the cost-effectiveness of AAT replacement therapy would be comparable to widely used medical interventions, including antihypertensive medications, coronary bypass, antihypercholesterolemia medications, and estrogen replacement therapy. It seems apparent that smoking avoidance by AAT-deficient nonsmokers and cessation among AAT-deficient smokers would be highly clinically effective and cost effective as primary preventive strategies.

The results presented here are somewhat conservative in calculating benefits for several reasons. First, it is likely that a large percentage of adults would be able to receive AAT replacement therapy at an annual cost less than $30,000, even when the cost of treating side effects is included. Also, it is likely that improvements in therapeutic administration and reductions in the cost of producing Prolastin will occur as new technologies are developed. Additionally, COPD medical costs and patient survival after the onset of symptoms are likely to continue their upward trends; both of these developments would enhance the cost-effectiveness of therapy designed to reduce or delay the probability of COPD incidence. Because of lack of data, we did not include any medical costs for mild stages of COPD disease. However, based on our sensitivity analysis, this last bias is probably quite small: a 40 percent increase in annual medical costs (or in missed medical costs) would only improve the estimated therapy benefits by 2–4 percent (Table 3). Finally, because of data and methodology limitations, we have ignored important positive and negative quality-of-life considerations, including those associated with routine IV therapy and with the pain and suffering of avoided disease.

More precise cost-effectiveness values could be calculated if we knew whether AAT replacement therapy is effective in improving patient outcome and, second, whether it merely halts progression of disease or improves lung function. Most of the anatomical changes associated with AAT deficiency are considered irreversible. We also need to know whether the use of AAT replacement therapy before clinical disease onset will prevent the development of emphysema in later life. If therapy is found to be efficacious, the timing of therapy initiation in relation to the course of COPD disease will also be of crucial clinical and economic significance. These issues can only be resolved by randomized, controlled, prospective double-blind studies. Such studies should antedate any widescale use of therapy or broad-based screening programs.

Randomized controlled clinical trials of AAT therapy designed to detect minimally significant clinical differences might inadvertently allow for ineffective economic results. The "outcome efficacy" survival benefits would have to be substantial for the intervention to be readily cost-justified. Such benefits could be detected in a relatively small clinical trial. Similar economic considerations would also have implications for other therapies and biomedical research issues. ☐

APPENDIX

CLYS cost-effectiveness estimates have been developed for a number of medical technologies and thus provide a convenient and widely accepted comparative perspective on this intervention relative to other well-known medical interventions.[10-12] CLYS values provide estimates of the net cost of saving one additional year of life. CLYS is measured as:

$$\text{CYLS} = \Delta C/\Delta Y. \tag{1}$$

The net change in COPD medical cost, ΔC, includes the present value of lifetime AAT replacement therapy costs plus costs of treating any therapeutic side effects, while subtracting out the average savings in COPD treatment costs resulting from reduced probability of disease. The increase in life years resulting from intervention, ΔY, is calculated as the average increase in patient life expectancy, plus a fraction of the average reduction in patient COPD disability days.

Emphysema patients report more days of restricted activity and work loss than average, even after age- and sex-adjustment. National Center for Health Statistics data on the annual age- and sex-specific number of restricted activity days associated with emphysema are 66.8, 0.1, and 28.7 for men age 21–40, 41–60, and 61 or older, respectively, and are 143.8, 0.6, and 26.2 for women 21–40, 41–60, and 61 or older, respectively.[27] Quality-adjusted life year (QALY) measurements are often used to weigh episodes of illness (in days) with 1 representing perfect health and 0 representing death.[12] Various methods have been developed to calculate QALY weights. We arbitrarily chose to weigh restricted activity days at 75 percent of healthy days in our base-case analysis. As shown in Table 2, since the average number of emphysema disability days is small relative to the average reduction in life expectancy, any weight between 0 and 1 has little impact on cost-effectiveness estimates. It should be pointed out, however, that CLYS estimates that disregard change in disability days would implicitly assume that a day of illness is equivalent to a day of health.

Change in survival was calculated by adjusting Larsson's age-, sex-, and smoking-status-adjusted five-year PiZ hazard rates by the ratio of age- and sex-adjusted US average population hazard rates to Swedish non-PiZ subject hazard rates (see Table A.1). Column one of Table 1 has projected this survival data to the reductions in life expectancy associated with AAT deficiency for age-, sex-, and smoking-status-adjusted US cohorts.

CLYS Estimates

The CLYS estimation equations can be described iteratively, just as they are calculated in a computer spreadsheet. Abstracting from sex and smoking status variations, let λ_t be the discrete mortality hazard at patient age t for intervals of length τ (e.g., $\lambda_t = 0.22$ in the five-year interval for smoking males age 25-29; Table A.1). Then L_t, the discounted life expectancy at age t obeys;

$$L_t = D_{\tau/2}\lambda_t\,(\tau/2 - \delta) + D_\tau[(1 - \lambda_t)\,(\tau d + L_{t+1})], \tag{2}$$

where D_τ and $D_{\tau/2}$ are the time discount factors for time intervals of length τ and $\tau/2$, respectively; δ is the estimated cumulative time lost due to disability, discounted forward from the median time of COPD diagnosis to the midpoint of the τ-year interval when death from COPD occurs, and d is a survivor discount factor to adjust the τ years of survival forward to the end of the interval. Equation (2) contains discrete-time approximation errors, since we are assuming that the average death occurs at the midpoint of the time interval, when it is actually more likely to occur somewhat later in the interval. Also, as in the US Vital Statistics tables,[28] all individuals over age 85 are combined into final sex-specific age categories. These simplifications do not substantially affect the results.

Let λ^p_t be the τ-year hazard for a (sex-, smoking-adjusted) PiZ individual, λ^e_t be the τ-year hazard associated with a therapeutic efficacy of 100e percent, and λ^n_t be the τ-year hazard for a normal individual. Then we define "outcome efficacy" as;

$$\lambda^e_t = \lambda^p_t - (\lambda^p_t - \lambda^n_t)e. \tag{3}$$

One hundred percent efficacy would mean normal survival and 0 percent efficacy would mean the same mortality hazard as an untreated PiZ individual. Using equation (2), we define L^e_t to be the estimated life expectancy with therapy and L^p_t to be life expectancy without therapy. ΔL^e_t, the change in life expectancy at age t associated with a therapeutic "outcome efficacy" of e, would then obey;

$$\Delta L^e_t = L^e_t - L^p_t. \tag{4}$$

In the absence of therapy, excess medical costs due to PiZ-related COPD would obey:

$$M_t = D_{\tau/2}[(\lambda^p_t - \lambda^n_t)\,C_1] + D_\tau[(1 - \lambda^p_t)\,M_{t+1}], \tag{5}$$

where C_1 are the medical costs for treating fatal COPD discounted forward to time of death. The base-case analysis assumes that an average COPD fatality would experience a course of illness requiring annual medical treatments costing $14,647 per year during an eight-year period prior to death. This is a conservative estimate of medical costs, since costs are excluded for PiZ-related disease insufficiently severe to cause death, and for COPD prior to illness severity meeting the criteria in the Strauss *et al*, Bergner *et al* and Burrows *et al* studies.[8,9,17] As detailed in the text above, these downward biases on our medical cost estimates do not have a large effect on the CLYS calculations.

Under therapy, the medical and intervention costs due to PiZ-related COPD would obey;

$$M^e_t = D_{\tau/2}[(\lambda^e_t - \lambda^n_t)\,(C_1 + C_2/2)] + D_\tau[(1 - \lambda^e_t)\,(C_2 d + M^e_{t+1})], \tag{6}$$

where C_2 are the τ-year therapeutic intervention costs, including treatment of side effects or adverse reactions, discounted to the midpoint of the interval. In our base-case analysis, these are assumed to be $30,000 per year, or $146,733 per five-year interval using a 5 percent discount rate.

ΔM^e_t, the change in medical costs at age t associated with a therapeutic "outcome efficacy" of e, would obey;

$$\Delta M^e_t = M^e_t - M_t. \tag{7}$$

Thus, our measure of CLYS associated with a therapy of "outcome efficacy" e is $\Delta M^e_t/\Delta L^e_t$.

Clinical Trial Power Calculations

The two-tailed power estimate $1 - \beta$ for clinical trial sample sizes with a significance level of $\alpha = .05$ is calculated using the binomial probability formula;

$$\beta = \Phi\{[N^{1/2}(P_0 - P_1)]/[|P_0(1 - P_0) + P_1(1 - P_1)|^{1/2}] - 1.96\}, \tag{8}$$

where $\Phi\{\cdot\}$ is the cumulative normal distribution function, N is the sample size per treatment arm, P_0 is the (five-year) control group mortality rate, and P_1 is the treatment group mortality rate.[23]

Population Screening Cost Estimates

The estimated screening costs were calculated for the US population. It was assumed that, excluding the young and the elderly, there were about 100 million adults who might be considered for screening. Of these, roughly 30 percent would be current or recent smokers, and 10 percent would be emphysema patients. Twenty percent would be geneal relatives of emphysema patients. Screening costs, including follow-up testing of initial positives were estimated at $110 per screenee. It was assumed that the full battery of screening tests would be performed for all geneal relatives (assumed to average 3.3) of identified AAT-deficient adults. As described in the text, we assumed a false positive rate of 1 percent.

Regular Source of Ambulatory Care and Access to Health Services

Rodney A. Hayward, MD, Annette M. Bernard, MD, MSPH, Howard E. Freeman, PhD, and Christopher R. Corey, MA

ABSTRACT

Background: To examine why people lack a regular source of ambulatory care (RSAC) and explore whether this commonly used access measure accurately identifies population subgroups at risk for barriers to continuity care.

Methods: Using data from a 1986 national telephone survey, we performed a content analysis of subjects' verbatim reports as to why they lacked an RSAC (n = 5,748).

Results: The 16.4 percent of respondents who lacked an RSAC gave the following reasons: 1) financial problems, 8 percent; 2) local resource inaccessibility, 5 percent; 3) not wanting a regular source of ambulatory care, 61 percent; and 4) transitory loss of their regular source of ambulatory care, 18 percent. However, some sociodemographic subgroups reported substantially more problems with access barriers, and these disparities were often not detected by the global measure, RSAC. The poor were not more likely than the non-poor to lack an RSAC (odds ratio [OR] = 0.8; 95% confidence interval, [0.6, 1.1]), but were much more likely to lack an RSAC for financial reasons (OR = 5.2 [2.6, 10.6]). Similarly, rural respondents were not more likely than urban dwellers to lack an RSAC, but were more likely to lack an RSAC because of local resource inaccessibility (OR = 5.8 [2.8, 11.9]).

Conclusions: We conclude that the global measure, RSAC, is not an accurate indicator of whether population subgroups have access barriers to obtaining a source of continuity care. (*Am J Public Health* 1990; 81:434–438)

Introduction

Substantial effort and funds are devoted to monitoring access to health services in the United States.[1–10] Whether or not people have a regular source of ambulatory care has been a traditional measure in surveys on access and use of health services.[4–7,9,11–12] It has been recognized that access problems, such as financial barriers and provider unavailability, are not the only reasons for not having a regular source of ambulatory care.[13–14] Yet this indicator is often used to compare the access to continuity of care for different sociodemographic subgroups. It is sometimes assumed that the absence of a regular source of ambulatory care is primarily accounted for by access barriers. Whether or not this characteristic identifies groups that are at high risk of not receiving continuity of care because of access barriers has not been critically evaluated.

To evaluate the usefulness of this indicator as a measure of health services access, we analyzed data from the 1986 Robert Wood Johnson Foundation's access to health care survey. The analyses had three main objectives: 1) to identify the reasons Americans lack a regular source of ambulatory care; 2) to examine whether or not such reasons vary by demographic subgroup; and 3) to determine if the absence of a regular source of ambulatory care identifies sociodemographic subgroups at high risk for not obtaining continuity of care because of access barriers.

Methods

This 1986 national telephone survey used random-digit dialing and had a response rate of 76 percent. The Waksberg screening procedure was used to minimize the number of nonworking numbers dialed.[15] Persons with chronic or serious medical illnesses were oversampled to allow for adequate evaluation of access problems of persons with major health problems. The results presented are weighted to produce estimates for the US population. Detailed descriptions of the weighted-probability sampling technique have been published previously,[5,8,10,16] and the interview and schedule data are available from the Inter-University Consortium for Political and Social Research at The University of Michigan. Weighted and unweighted sample sizes by social characteristics are presented in the appendix.

As part of the survey, each interviewee was asked, "Is there one person or place in particular you usually go to when you are sick or want advice about your health?" Those who answered "no" to this question were asked: "Many people do not have one particular place to get medical care. What is the reason that you do not have a regular doctor or place to go?" Interviewers were instructed to record the responses to this item verbatim.

The survey on access to health care sampled 10,130 Americans, but verbatim responses were stored for a subset of the

interviewees; this subset consists of consecutive cases obtained by random-digit dialing (n = 5,748), and there are no substantive differences between this subset and the overall sample with respect to key variables (regular source of ambulatory care, age, sex, geographic region, income, ethnicity, or insurance status).

To aid in developing a classification system for categorizing verbatim responses, we asked 20 health care providers to list reasons that people lack a regular source of ambulatory care. This generated a list of 82 specific reasons. This list was then simplified into a five-category classification structure: 1) financial problems; 2) local resource inaccessibility; 3) did not want a regular source of ambulatory care (divided into four subgroups, described below); 4) transitory loss of their regular source of ambulatory care; and 5) no response or response not classifiable. Pilot testing of a sample of actual responses revealed high reliability, and reviewers did not feel that further revisions of the classification structure were needed.

Financial problems included being unable or unwilling to pay the expected cost of medical care. Local resource inaccessibility included those who reported an inadequate supply of health care providers in their area or who reported logistical problems with getting care (i.e., problems with parking, transportation, or contacting their health care provider).

Two investigators (RAH and AMB) independently reviewed and categorized all verbatim responses. Inter-rater agreement was 96 percent for classification into the five main categories and 94 percent for classification into categories and subcategories. Upon joint review, most disagreements were easily resolved, and when reviewers continued to differ, the response was designated as non-classifiable.

Analyses were performed on five dependent variables: 1) the proportion who did not have a regular source of ambulatory care, and the proportion who lacked a regular source of ambulatory care because of 2) financial problems; 3) local resource inaccessibility; 4) not wanting one; and 5) transitory loss of a regular source of ambulatory care. Each variable was broken down according to eight respondent characteristics: age, sex, self-reported health status, household income, ethnicity, education, medical insurance status, and urban vs. rural residence. For respondents age 22 or younger, main wage earner's education was used.

We also evaluated associations between having a regular source of ambulatory care and receipt of cervical and breast cancer screenings;[10] seeking a physician for serious medical symptoms;[17] and needing medical, surgical, or supportive medical care and not being able to obtain it.[5,8] We measured receipt of care for serious symptoms using a method developed by Shapiro et al.[17–18] Each respondent was asked serially about one of five serious symptoms: 1) shortness of breath with light exercise or light work: 2) chest pain while exercising; 3) loss of consciousness; 4) abnormal bleeding; and 5) weight loss of 4.5 kb. or more not caused by dieting. Subjects who reported one or more serious symptoms during the past month were reported as having sought care if they had contacted a physician for any of the symptoms.

Results

Overall, 17.0 percent of respondents reported not having a regular source of ambulatory care. However, analysis of verbatim responses found that 0.6 percent of these respondents had misunderstood the question and actually had a regular source of ambulatory care. Most errors were due to subjects thinking they were being asked if they saw their doctor regularly (i.e., "I have a family doctor, but I don't go in that often."). Correction of these errors did not alter any of the associations between a regular source of ambulatory care and the respondent characteristics. This paper presents results using corrected responses.

After correction for the errant responses, we found that 16.4 percent of all respondents lacked a regular source of ambulatory care (Table 1). Bivariate comparisons showed that those aged 13 to 44 were more likely than other age groups to lack a regular source of ambulatory care. Also, not having a regular source of ambulatory care was more common among the uninsured, those in excellent or good health, males, Hispanics and Blacks.

Table 2 shows the reasons respondents lacked a regular source of ambulatory care, as a percentage of those lacking a regular source of ambulatory care and as a percentage of the total sample. Of the 841 respondents who reported not having a regular source of ambulatory care, 8 percent reported not having one because of

TABLE 2—Reasons for Lacking a Regular Source of Ambulatory Care (RSAC)

Reason for Not Having an RSAC	Percent of Those Who Lack an RSAC (n = 841)	Percent of All Respondents (n = 5,748)
Financial problems	8	1.4
Local resource inaccessibility	5	0.8
Did not want an RSAC	61	9.9

Transitory loss of RSAC	18	2.9
No response/unintelligible	8	16.4%
Lack an RSAC	100%	16.4%

financial barriers, and 5 percent because of local resource inaccessibility. In contrast, 61 percent reported not wanting a regular source of ambulatory care; most of these reported not having perceived a need for care. In addition, 18 percent reported a transitory loss of their regular source of ambulatory care, and 8 percent had no answer available. Overall, 2.2 percent of all respondents reported lacking a regular source of ambulatory care because of financial barriers or local resource inaccessibility (Table 2).

To evaluate the relative associations between the respondents' sociodemographic characteristics and the dependent variables (no regular source of ambulatory care and the four reasons people reported not having a regular source of ambulatory care), we computed logistic regression models for each dependent variable (Table 3). Respondents aged 13–44 were more likely than those in other age groups not to have a regular source of ambulatory care. This difference was distributed among the four reasons for lacking a regular source of ambulatory care (Table 4). Those in excellent or good health were more likely to lack a regular source of ambulatory care, chiefly because of not wanting one. Men were more likely than women to lack a regular source of ambulatory care due to a greater likelihood of having financial problems, not wanting a regular source of ambulatory care, and transitory loss of their regular source of ambulatory care (Table 3). The uninsured were more likely than the insured to lack a regular source of ambulatory care, due to a greater likelihood of having financial problems, not wanting a regular source of ambulatory care, and transitory loss of their regular source of ambulatory care.

The poor were not found to be more likely than the non-poor to lack a regular source of ambulatory care, but were more likely to lack a regular source of ambulatory care for financial reasons (Table 3). Similarly, level of education and place of residency were not associated with having a regular source of care, however, those with less education were more likely to report a financial barrier to obtaining a regular source of ambulatory care, and rural respondents were much more likely . . ." Level of education was even less likely to be associated with having a regular source of ambulatory care, but those with less education were more likely to report a financial barrier to obtaining a regular source of ambulatory care (Table 3). Yet rural respondents were much more likely to lack a regular source of ambulatory care because of local resource inaccessibility (Table 3). In all these instances, the global measure, regular source of ambulatory care, failed to identify those with greater risk for having access barriers to a regular source of ambulatory care.

However, lacking a regular source of ambulatory care was a risk factor for not receiving recommended medical care (Table 4). Those who did not have a regular source of ambulatory care were less likely to have received breast and cervical cancer screening and to have seen a physician when they had a serious medical symptom, and they were more likely to report being unable to obtain medical or surgical care they needed during the past year. They were also less satisfied with the medical care they had received.

Discussion

Whether or not people have a regular source of ambulatory care has been a commonly used process measure of access and is used as an indicator of whether the respondent has a source of continuity of care. Having a regular source of ambulatory care is felt to be particularly important for those with chronic conditions as well as for maternity and child care. Whether having a source of continuity of care improves efficiency or promotes better quality of care has not been well studied, and our results do not shed light on this issue. However, we did find that lacking a regular source of ambulatory care identifies a group that is less likely to receive recommended health services and that is less satisfied.

The presence or absence of a regular source of ambulatory care is also used to evaluate different population subgroups' access to obtaining a source of continuity of care. In this study, we found that the global measure, regular source of ambulatory care, could not be relied upon for this purpose. First, we found that most people who lack a regular source of ambulatory care do not report access barriers as the reason. Only 13 percent of those who lacked a regular source of ambulatory care reported problems with finances or availability of local health care providers, whereas 61 percent reported not wanting one. Although each study employed slightly different classification structures, our findings of why people lack a regular source of ambulatory care are consistent with previous reports.[13–14]

Second, in most instances, regular source of ambulatory care was a poor indicator of which groups were more likely to have access barriers to obtaining continuity of care. For instance, rural respondents were no more likely than urban respondents to lack a regular source of ambulatory care; however, a rural residence was the only major risk factor for having problems with local resource inaccessibility. Therefore, relying upon the global measure would be misleading in terms of the importance of access problems for rural residents in obtaining a source of continuity of care. Similarly, of the three variables most strongly associated with lacking a regular source of ambulatory care due to financial problems, two (household income and level of education) were not associated with the global measure, regular source of ambulatory care.

This study has several limitations. Telephone surveys bypass the 5 percent to 10 percent of the population who do not have telephones, resulting in underrepresentation of the poor, elderly, and uninsured,[19–21] groups that are particularly at risk for access problems. Still, supplemental face-to-face interviews con-

*Poor is defined as household income <100 percent of the federal poverty level, near-poor is 100–150 percent of the poverty level, and non-poor is more than 150 percent of this level.

†Includes those with some college.

ducted in 1986 demonstrated, as others have found,[19–21] that inclusion of nontelephone households would affect percentage estimates only slightly. Nonetheless, small percentage differences in national surveys can represent millions of people. Furthermore, both survey techniques completely miss the homeless and those in institutions. In addition, the results are self-reported and are therefore dependent upon the reliability of respondents' recall. We are not able to determine whether population subgroups have different thresholds in reporting an access barrier. Also, 1.4 percent of respondents did not have a classifiable verbatim response. Although we found no pattern of one group being statistically more likely to have no available response, it may be that some of the weaker associations or trends might have been altered if responses had been complete. Finally, some of those who have a transitory loss of their regular source of ambulatory care or do not currently want one, may have unreported access barriers or may encounter access problems if and when they try to obtain one.

TABLE 4—Receipt of Recommended Medical Care and Patient Satisfaction among Those with and without a Regular Source of Ambulatory Care (RSAC)

	Have an RSAC %	Do not have an RSAC %	Differences (95% CI)
Pap smear within the past year*	56	46	10 (3, 17)

*For women 20 years or older.

†For women 40 years or older.

**For women 50 years or older.

††Percentage of those respondents who had 1) shortness of breath with light exercise/work; 2) exertional chest pain; 3) loss of consciousness; 4) abnormal bleeding; or 5) unexplained weight loss during the past month, and who saw or spoke to their doctor about it.

We conclude that most people who do not have a regular source of ambulatory care report that they do not want one, and the global measure, regular source of ambulatory care, fails to identify hose sociodemographic subgroups who are at greater risk of having barriers to obtaining a source of continuity of care. Therefore, if we are truly interested in who is at risk for access barriers to obtaining continuity of care, the reason for lacking a regular source of ambulatory care must be evaluated. ☐

A Community-Based Study of the Use of Chiropractic Services

Paul G. Shekelle, MD, MPH, and Robert H. Brook, MD, ScD

ABSTRACT

Background: Little population-based information is available on the use of chiropractic services.

Methods: We analyzed data from the RAND Health Insurance Experiment (HIE), a community-based study of the use of health services. Insurance claim forms for all fee-for-service patients who completed the study were examined for all visits coded as being seen by a chiropractor. Services provided and patient-specified symptoms were taken from these forms. Population-based use rates were calculated for each HIE site. Use rates and services were calculated separately for first visits and repeat visits.

Results: There were 5,279 persons who contributed 19,021 person-years of exposure during the study; 395 different persons used 7,873 chiropractic services for a visit rate of 41 per 100 person-years and rate of use of 7.5 percent. Forty-two percent of all visits were for pain in the back. Spinal manipulation accounted for 61 percent of all services provided. Compared to non-users, users tended to be White, middle-aged, married, and high school educated. Seven-fold geographic variations in the use of chiropractic services were seen.

Conclusions: Chiropractors deliver a substantial amount of health care to the US population, and there are significant geographic variations in the rate and intensity of use of chiropractic services. (*Am J Public Health* 1991;81:439–442)

Introduction

Previous studies of the use of chiropractic services have used patient samples that were obtained from selected chiropractors' offices or clinics.[1–8] Such studies have shown that chiropractic users are more likely to be middle-aged, employed, and high school educated. No difference in gender has been seen. Most studies have shown use among races in proportion to their representation in the population, but one study reported significantly greater use by Whites.[2] Low back pain is the most common complaint of patients seeking chiropractic care (from 32 percent to 45 percent, depending on the study), and spinal manipulation is the most frequently provided service (from 76 percent to 92 percent of all services). Population-based use rates cannot be estimated from these studies. Therefore, we analyzed data from a prospective, large-scale, community-based population to answer the following questions: How many people use chiropractic services? What are their demographic characteristics? For what symptoms do they seek care? What services are provided? Are there geographic variations in use?

Methods

The RAND Health Insurance Experiment was designed to assess how varying the patients' share of costs for health services affected their use of services, their satisfaction with health care, the quality of their care, and the state of their health. Eligibility, enrollment, data collection, and principal results have been reported elsewhere.[9]

In brief, the study was conducted between 1974 and 1982 at six sites: Seattle, Washington; Dayton, Ohio; Fitchburg, Massachusetts; Franklin County, Massachusetts; Charleston, South Carolina; and Georgetown County, South Carolina. These sites were chosen to represent the four major census regions, both rural and urban areas, and differing levels of demand for health services. The population enrolled in the experiment, which was entirely civilian and under age 65, has been shown to be representative (across a wide range of variables) of the communities from which it was drawn and of the US population aged younger than 65.[10] Each enrollee was randomized to one of 14 fee-for-service insurance plans. All plans covered an identical wide range of services, including chiropractic care. Families were followed for three to five years.

Insurance claim forms of all fee-for-service patients who completed the study were examined for patient visits that had been coded as visits to a chiropractor. The symptoms we report here were the symptoms reported by the patients on their insurance claim forms as reasons for the visits. We took the services provided to be those for which reimbursement was sought by the chiropractor: visits, manipulations, X rays, laboratory tests, etc. Some patients and providers may have recorded more symptoms than others for equivalent conditions. We adjusted for this possibility in the following way. If multiple symptoms were recorded for a

[a] For adults age 18 or older.

single visit, each symptom was given a simple fractional weight so that for each visit the total symptom score summed to 1.0 (e.g., if two symptoms were recorded, each was given a weight of 0.5). Symptoms and services are presented here both as percentages and in terms of 100 person-years of exposure. A person-year was defined as a 12-month period beginning on date of enrollment (or anniversary date of enrollment) in the Health Insurance Experiment (i.e., not a calendar year). Population-based use rates were calculated for each Health Insurance Experiment site. Use rates and services provided were calculated separately for both the first patient visit and the repeat visits. First visits and repeat visits were defined by a specific code on the insurance claim forms to indicate whether the patient had seen this particular provider before. Because we could not calculate the number of visits on a per-episode basis, we calculated the number of chiropractic visits per person-year.

Results

The 5,279 people who completed the Health Insurance Experiment were enrolled for three or five years and represented a total of 19,021 person-years of exposure. During the study, 395 different persons (7.5 percent) made at least one visit to a chiropractor: 7,873 visits in all, or 41 chiropractic visits per 100 person-years. Repeat visits accounted for 82 percent of all visits. Only 1 percent of visits did not involve a face-to-face meeting between the patient and the chiropractor. Fewer than 1 percent of the visits were referred from another health care provider (either a physician or another chiropractor), seven percent of all visits were accident-related, and 1 percent were employment-related.

The 395 persons who saw chiropractors visited a chiropractor at least once during 683 person-years. In almost 40 percent of these person-years there were five or fewer chiropractic visits per year (Figure 1), and in 75 percent of them there were 15 or fewer visits per year. The median number of visits per year was seven and the mean was 11.5. In 13 person-years there were more than 50 visits per year, and these person-years contained 780 visits.

Table 1 compares the demographic characteristics of the chiropractic users with those of the nonusers. Chiropractic users were more likely to be White, aged 18–50, married, and high school graduates.

The most frequently given reason for a chiropractic visit (42 percent) was pain, swelling, or injury to the back region (Table 2). This symptom plus "back adjustment" accounted for 50 percent of visits overall, and this value varied from 41 percent to 69 percent, depending on the site.

Table 3 shows the services provided during the Health Insurance Experiment for the 395 chiropractic patients, by first visit and repeat visits. In the first chiropractic visit, manipulation (39 percent) accounted for the majority of services, but physical medicine visits (23 percent), office visits (19 percent), and X rays (17 percent) together accounted for almost 60 percent of the total services. Manipulation (66 percent) accounted for the majority of services provided for repeat visits, with physical medicine visits, office visits, and X rays accounting for 32 percent.

The frequency of chiropractic visits varied widely among the six Health Insurance Experiment sites (Table 4). The number of persons seeking care per 100 person-years ranged from 0.6 (Charleston) to 3.1 (Seattle). The number of services per 100 person-years on first visits and repeat visits varied from a low of 3.5 and 9.5, respectively, in Dayton and Charleston, to a high of 23.8 and 86.0, respectively, in Georgetown County, South Carolina.

Discussion

Our community-based study demonstrated a chiropractic visit rate of 41 per 100 person-years of exposure and that 7.5

TABLE 2—Patient-Specified Reasons for Chiropractic Visits

Reason for Visit[a]	Per 100 Person-years (N = 19,021 Person-years)	%

All others	0.1	1.0	0.6	1.2
Total	4.2	100.0	45.5	100.0

percent of a community will use a chiropractor's service in a three- or five-year period. These numbers are somewhat lower than the 62 visits per 100 person-years and visit rate of 3.6 percent per year during the same time period that have been reported in the 1980 report to Congress on Manpower in the Chiropractic Profession.[4] Our study confirms previous observations that chiropractic users tend to be middle-aged and high school educated and that users do not differ from nonusers in their gender and income. We observed a greater use of chiropractic services by Whites, as also seen in one other survey.[2]

In previous studies, the average number of visits per user per year has varied between 5[6] and 18.[4] Our data, with a median of 7 and an average of 11.5, show that chiropractic use has a substantial tail to the right. In 13 person-years there were 50 or more visits per year. These 13 person-years (2 percent of the total person-years examined) contained 10 percent of the total number of visits. Results from the National Medical Ambulatory Care Survey between 1975 and 1980 showed that 7.7 visits per 100 person-years for back pain were made to physicians.[11] Our study showed that, during approximately the same time period, there were 17.4 visits per 100 person-years to chiropractors for the same complaint. Therefore chiropractors accounted for about twice as many visits for back pain as did physicians, as has been shown before.[12]

Symptoms of back pain accounted for 42 percent of patients visits. This finding is similar to 45 percent reported in Dade County, Florida;[5] 44 percent from Portland, Oregon[6]; and 32 percent from Tucson, Arizona.[8] This consistency from different geographic areas and time periods suggests that the symptoms for which patients seek chiropractic care vary little across the country.

Spinal manipulation, although still accounting for the majority of services provided, accounted for somewhat less than the 76 percent to 92 percent previously reported. In addition, there were differences in the types of services provided on the first visit and repeat visits. The typical first visit to a chiropractor appeared to consist of an office visit and/or physical medicine visit; most patients received an X ray and then manipulation. Repeat visits consisted of manipulation, with or without an additional office visit, and no further X rays. Because most chiropractic treatments involve a series of manipulations, it is not surprising that the number of manipulations far exceeded the number of office visits. As in previous studies, X rays and laboratory tests accounted for a relative minority of the total services.

First-visit use and repeat-visit use showed sevenfold and ninefold geographic variations, respectively, in chiropractic use in the Health Insurance Experiment. A previous study[4] had noted variations in chiropractic use, with greater use in the west and north-central regions of the US than in the South or Northeast. Our data cannot confirm these findings. In addition, Seattle and Charleston (both urban areas) had fourfold differences in use; Franklin County and Georgetown County (both rural) showed threefold differences in use. There was also substantial variation within a geographic area: the two southern sites exhibited the widest variation in use of chiropractic services.

The major limitations to this study are that its data are a decade old and that the elderly were excluded from the population. It has been estimated that the use of chiropractic services has been increasing during the past 20 years,[6] and the rate of use may be greater today than was seen in the RAND Health Insurance Experiment. A previous study of chiropractic use[2] reported that patients over age 65 accounted for 13 percent of the total number of chiropractic patients, and therefore we expect that excluding the elderly from our study will not qualitatively alter its conclusions. With these caveats, out study, because of its community-based design, provides an unbiased estimate of the use of chiropractic services, and documents that there are significant geographic vari-

TABLE 4—Use of Chiropractic Services for First Visit and Repeat Visits per 100 Person-Years, by Study Site

Site	Number Seeking Care per 100 Person-years	Services Used per 100 Person-years	
		First visit	Repeat visits

$7.5 Million Grant Program to Strengthen State Data Systems

The Robert Wood Johnson Foundation recently announced a $7.5 million grant program to be made available to state policy-makers to provide them with more accurate, up-to-date data about health care issues.

In the first phase of the program, up to 10 states will be awarded grants of up to $150,000 each to identify gaps in health policy and program information, and then to develop plans to fill them. Grant project directors will review information needs and set priorities, establish short- and long-term plans, and develop a specific proposal for enhancing existing data systems or for creating new ones to meet high priority information needs.

Each grant will be carried out by a lead government agency designated by the governor, and a working group composed of analysts from other state agencies, the legislature, state health program managers, health data agency representatives, private sector organizations, consumer groups, and others.

Based on the strength of the plans developed during the 18-month grant period, the RWJ Foundation will award as many as six four-year grants for amounts up to $1 million each; these grants will be used to develop and test the planned data system improvements, for data collection, analysis and dissemination.

The deadline for submitting proposals is August 1, 1991. Grant applicants must be state government agencies. An information conference for potential applicants is scheduled for May 1991.

Agencies wishing to apply for funds should contact: Ann P. Pomphrey, Program Assistant, Robert Wood Johnson Foundation, Route 1 and College Road East, P.O. Box 2316, Princeton, NJ 08543-2316. Technical assistance to the program will be provided by Ruth S. Hanft, PhD, research professor, Department of Health Services Management and Policy, George Washington University, Washington, DC.

Morbidity and Disability in Older Persons in the Years Prior to Death

37

Jack M. Guralnik, MD, PhD, Andrea Z. LaCroix, PhD, Laurence G. Branch, PhD, Stanislav V. Kasl, PhD, and Robert B. Wallace, MD

ABSTRACT

Background: A large proportion of the disease and disability which affects older persons occurs in the years just prior to death. Little prospective evidence is available which quantifies the burden of morbidity and disability during these years.

Methods: In three community-based cohorts of persons age 65 and older, chronic conditions and disability were evaluated for the three years prior to death in 531 persons who had three annual assessments and then died within one year of the third assessment. Number of chronic conditions, prevalence of disability in activities of daily living (ADLs), and prevalence of disability on a modified Rosow-Breslau scale were determined for these decedents and compared to 8821 members of the cohorts known to have survived.

Results: Prevalence rates of disease and disability increased during the follow-up for both decedents and survivors, with decedents generally having higher rates than survivors. Disability rates prior to death, but not the number of diseases, increased with increasing age at death. The odds ratio for disability in ADLs at any of the three assessments for decedents versus survivors ranged from 3.0 to 4.2 in the three communities. In each community the odds ratio for ADL disability was higher in women decedents versus survivors than in men decedents versus survivors.

Conclusions: These results have important implications for disability levels in future older populations in which death is projected to occur at increasingly higher ages. (*Am J Public Health* 1991;81:443–447)

Introduction

Prior to death, there is a decline in health status which may be quite variable. For the individual with a severe stroke who remains in a nursing home for several years, the state of poor health prior to death may be prolonged; for the person with metastatic cancer dying six months after diagnosis, duration of disability is moderate; and for the previously healthy individual who suffers sudden death, the state of poor health is virtually nonexistent. Just as the duration of poor health prior to death may be quite variable, its severity may also vary considerably. Increases in morbidity and disability prior to death have tremendous impact on individuals, their families, and the health care delivery system. With 71 percent of all deaths in the United States occurring among people age 65 and older,[1] it is of value to describe the systematic decreases in health status prior to death in this population.

The rising costs of caring for the older population have lead to a great deal of interest in the utilization and cost of health care in the years prior to death.[2] A study using Medicare data showed that 28 percent of all Medicare costs were incurred by the 6 percent of enrollees who would die within the next 12 months.[3] A study using data from the province of Manitoba was able to capture nearly all health care utilization in the years prior to death and found substantial increases in several measures of utilization with increasing proximity to death.[4]

Limitations are inherent in the use of health care utilization data to measure health status prior to death. Direct measures of disease and disability in older persons provide a more accurate description. There are a limited number of studies which examine disease or disability prior to death using either retrospective reporting of proxies[5,6] or prospective study designs.[7,8] In the present study, three representative populations of older persons were prospectively evaluated using self-report of common chronic diseases and two scales of physical functioning. The objectives of this analysis were to quantify the prevalence rates of disease and disability as death approached, compare these prevalence rates among decedents to rates in surviving members of the cohort, and examine how this process varies by gender and age at death. It was further hypothesized that disease and disability rates would increase to a greater extent in decedents than in survivors during the period of observation.

longitudinal studies of persons aged 65 and older. Participants included in these analyses were enumerated and interviewed in three communities in 1982 and early 1983. Details of study design and sampling strategies have been reported elsewhere.[9,10] Briefly, in East Boston, Massachusetts, and Iowa and Washington Counties, Iowa, full community surveys were conducted. A baseline response rate of 84 percent yielded 3,812 participants in East Boston, and in Iowa an 80 percent response rate yielded 3,673 participants. The New Haven target population was a stratified cluster sample of 3,420 eligible persons age 65 and older, drawn from three types of community dwellings: public elderly housing, where age and income are restricted; private elderly housing, where age is restricted; and private apartments and houses. There was oversampling of men and those living in elderly housing. A baseline response rate of 82 percent yielded 2,812 participants.

For the sake of clarity in understanding change in functional status and disease prior to death, these analyses were limited to a subset of participants for whom interview information was available for three consecutive years. The subjects of these analyses are those respondents from the three sites who participated in the baseline and first and second annual follow-up interviews and whose vital status was known for the next year of follow-up. Participants who died any time before the second annual follow-up were excluded from these analyses. Ascertainment of vital status at the end of the third follow-up year was nearly 100 percent at all sites.

Data Collection

The baseline interview was conducted in participants' homes and the first and second annual follow-up interviews were conducted by telephone or, if this was not possible, in person. A proxy interview was conducted for those unable to participate in the interview. Chronic conditions were assessed by asking respondents at baseline if they had ever been told by a doctor that they had a heart attack, stroke, cancer, diabetes, or hip fracture. At each follow-up interview, respondents were asked if they had been told by a doctor since the last interview that they had any of these conditions. Disability in activities of daily living (ADLs) was defined as self- or proxy-report of needing help from a person or special equipment in performing one or more of the following activities: walking across a small room, bathing, grooming, dressing, eating, transferring from bed to chair, or using the toilet.[11,12] Disability on a modified Rosow-Breslau scale of physical functioning was defined as the need for help in performing one or more of the following tasks: walking up and down stairs to the second floor, walking one-half mile, and doing heavy housework.[13] ADLs and Rosow-Breslau items were assessed at baseline and each annual follow-up.

Analytic Methods

Mean number of self-reported chronic conditions and prevalence of disability at baseline and at the first and second follow-ups were calculated separately for those dying in the one year period between follow-up 2 and follow-up 3 and for those surviving to follow-up three. The number of chronic conditions at each follow-up was calculated by determining the lifetime prevalence of each condition, taking into account baseline report as well as annual follow-up report of the occurrence of the condition in the previous year or years. Therefore, the number of chronic conditions for an individual could only stay the same or increase during the follow-up period. Individual reports of disability at each assessment were independent of other assessments.

Multiple logistic regression models were used to assess the odds of being disabled in any of the first three interviews for those dying between the second and third follow-ups compared to those surviving to follow-up 3.

Results

Table 1 shows the number of study participants who survived to follow-up 3 and who died between follow-ups 2 and 3 according to community, age group, and sex. There were 531 decedents and 8821 survivors in the communities by this definition. Those dying prior to follow-up 2 are not included in these numbers or in subsequent analyses.

In Figures 1, 2, and 3, the mean number of chronic conditions, the percent disabled in ADLs, and the percent disabled in Rosow-Breslau items and are shown for those dying between follow-ups 2 and 3 and those surviving to follow-up 3. Results are shown for baseline, follow-up 1 and follow-up 2 and are presented separately for each site, sex, and age group. For those dying between follow-up 2 and 3, the baseline data reflect morbidity and disability status from two to three years prior to death, the follow-up 1 data reflect status between one and two years prior to death, and the follow-up 2 data reflect status between zero and one year prior to death.

For nearly every site, sex, and age subgroup, the mean number of conditions and the proportion disabled was higher in those destined to die than in survivors. In most subgroups, these differences are evident even at baseline, which is two to three years prior to decedents' deaths. In general, mean number of conditions and disability prevalence rates increased as death approached. For those surviving to follow-up 3, there was also, for most subgroups, an increase in chronic conditions and disability from the baseline through the second follow-up interview. For some subgroups, the slope of the increase in de-

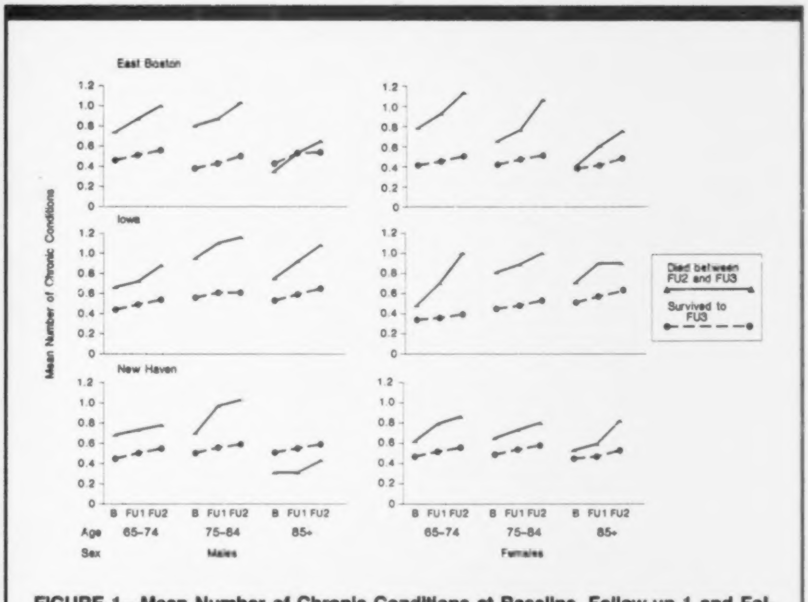

FIGURE 1—Mean Number of Chronic Conditions at Baseline, Follow-up 1 and Follow-up 2 According to Survival Status between Follow-up 2 and 3, Age Group and Sex; EPESE

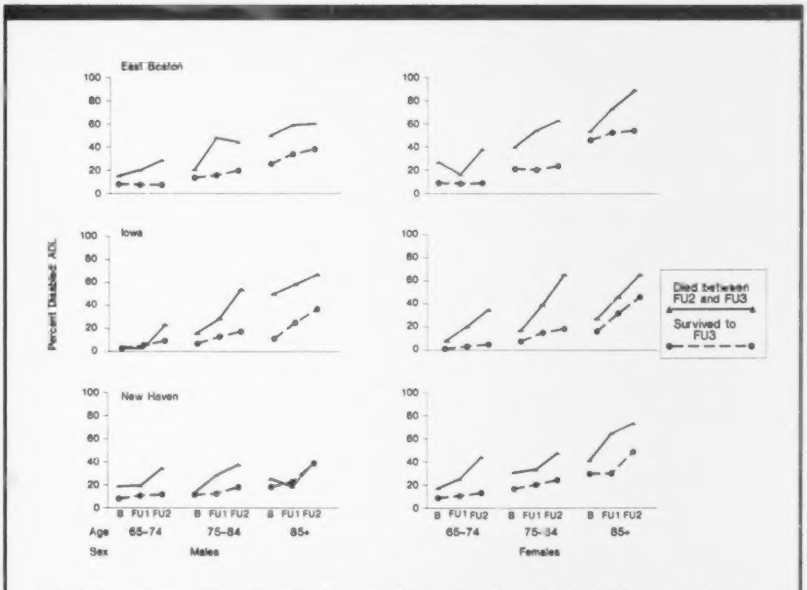

FIGURE 2—Percent Disabled in One or More Activities of Daily Living at Baseline, Follow-up 1 and Follow-up 2 According to Survival Status between Follow-up 2 and 3, Age Group and Sex; EPESE

cedents was clearly steeper than for the survivors, although this was not the case in all subgroups. In general, smaller differences were seen between decedents and survivors in the age group 85 years and older than for the two younger age groups.

Disability rates as measured by ADLs generally showed a substantial increase as death approached and were higher with increased age at death. In decedents aged 65–74 and 75-84 years at baseline, only about one-fourth or less report ADL disability at baseline, which was from two to three years prior to their deaths. At follow-up 2, within one year of death, the 65–74-year-old group had, in general, an ADL disability prevalence rate of 40 percent or less. In the 75–84-year-old group of decedents, up to two-thirds were disabled in ADLs in the year prior to death. Decedents aged 85 and older at baseline had the highest rates of ADL disability in the year prior to death (between 60 and 90 percent), with the exception of New Haven men.

Disability rates as assessed by the Rosow-Breslau items were higher in both decedents and survivors than corresponding rates of ADL disability. In the year prior to death, prevalence rates of disability, as measured by the Rosow-Breslau scale, were over 60 percent in nearly all subgroups, with those 85 and older having prevalence rates in excess of 80 percent. An increase in Rosow-Breslau disability rates with increased age at death was evident in most subgroups. Unlike disability measured by both instruments used here, mean number of chronic conditions prior to death did not show a consistent increase with age at death.

Table 2 demonstrates the magnitude of the differences in disability in ADLs in the baseline and first two follow-up interviews between those dying and those surviving. Odds ratios are presented for disability in any of these interviews for decedents compared to survivors. Overall, decedents were about three to four times as likely as survivors to report an ADL disability in either the baseline or first two follow-ups, after adjusting for age and sex. In men, decedents were 2.4 to 3.7 times as likely as survivors to report ADL disability. In women, the odds of disability in decedents was 3.7 to 5.2 times that of survivors. In each site, the odds ratio for disability for women who died versus survived was higher than the odds ratio for disability for men who died versus survived. The odds ratios for disability in decedents versus survivors by age group reveal no consistent trends with age across the three communities.

Discussion

Although the prevalence rates of disease and disability increase with age, there is no *a priori* reason to believe that within older populations those dying at a younger age should have less disability prior to death than those dying at older ages. These data reveal that those dying at the oldest ages generally have more disability, but not disease, prior to death than those dying at younger ages. As expected, the rates of disease and disability rise as death approaches, and those destined to die

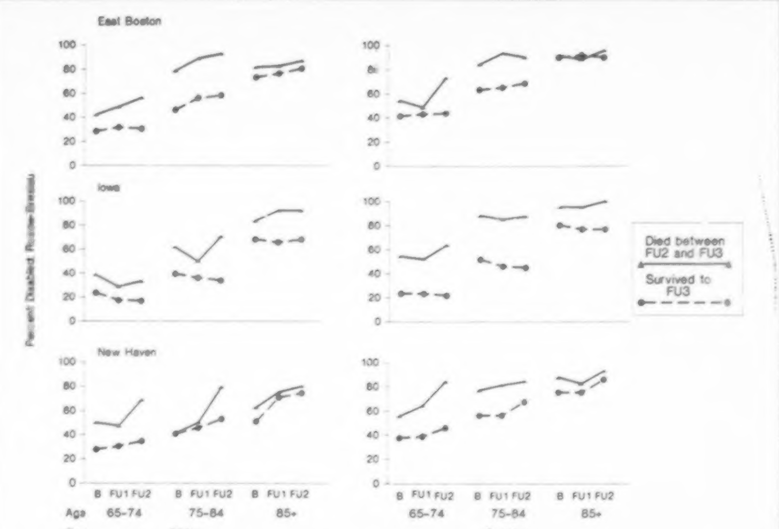

FIGURE 3—Percent Disabled in One or More Rosow-Breslau Items at Baseline, Follow-up 1 and Follow-up 2 According to Survival Status between Follow-up 2 and 3, Age Group and Sex; EPESE

have higher disease and disability rates than those of the same sex and age who survive.

In the conceptualization of these analyses, it was speculated that it might be possible to elucidate an even more refined relationship of morbidity and disability with death than we were able to demonstrate here. Consistent patterns were sought for differences in morbidity and disability during the three years of observation in decedents compared to survivors. Alternative patterns were postulated, including both groups starting out at the same disease or disability level and then diverging, the two groups starting out at different levels but remaining parallel, and the two groups starting out at different levels but still diverging during the years of observation. None of these patterns were observed in any consistent manner (Figures 1–3). This may be the result of methodologic shortcomings of this study or may reflect true variability in these relationships among different age groups, men and women, and the communities under study. A summary measure of ADL disability, that is, having any ADL disability in the three years prior to death, was employed to further investigate differences in sex and age relationships comparing decedents and survivors (Table 2). The odds of disability in decedents versus survivors showed no clear trend with age, but in each community the odds ratios for disability comparing decedents to survivors were higher in women than men.

A number of methodologic limitations must be considered in the interpretation of these results. The results in Figures 1–3 summarize percent disabled and mean number of conditions in a subgroup at a particular point in time, but changes for particular individuals as they approach death could differ considerably from these summary measures. It has been documented that change in functioning over time in individuals can be quite variable, with some reporting improvement, some reporting decline, and some reporting no change.[12,14] Research is now underway to analyze the multiple patterns of change which result from the repeated measures obtained in these longitudinal studies. These populations were all community-dwelling at baseline, although follow-up was completed for those entering an institution in subsequent years. Because rates of institutionalization increase dramatically with age, it is likely that the age gradient seen in disease and disability prior to death would be even steeper if all those in nursing homes three years prior to the deaths were included in the study. Although the cohorts under study are large, the number of deaths per year is not great and stratifying these deaths by age group and sex results in small sample sizes for certain subgroups. Larger numbers of deaths would have resulted in more accurate estimates of disease and disability prior to death and led to smoother curves for decedents in Figures 1, 2, and 3. The measures available to define morbidity and disability were fairly crude. The list of five chronic diseases was not comprehensive, being limited to those conditions queried at each interview. Disability status as estimated by both scales used here was dichotomized for ease of understanding and presentation. More refined scales, or perhaps the use of other measures which may be more sensitive to change over time, could lead to a finer understanding of the relationships investigated in this study. Finally, in comparing decedents to survivors there may be a "ceiling effect" which obscures the magnitude of differences in these two groups. This is seen, for instance, for the Rosow-Breslau scale for those aged 85 and older, in whom

the level of disability in survivors is so high that there may be little room for the decedents to appear more disabled (Figure 3).

There have been few prospective studies which have evaluated changes in disease and functional status prior to death. A number of studies have addressed terminal drop or terminal decline, but nearly all have focused on psychosocial or cognitive factors.[7] In a study which assessed declines in a number of domains, Palmore and Cleveland examined both terminal decline (defined as a steady, linear decrease prior to death) and terminal drop (defined as an accelerated decrease as death approaches) in 178 decedents in the Duke Longitudinal Study of Aging.[7] In a multivariate model, they found significant associations of both age and number of months prior to death with physical functioning. These results are in agreement with the findings presented here, as they can be interpreted to mean that, controlling for age at exam, there is decreasing physical functioning with increasing proximity to death, and, controlling for proximity to death, there is decreasing physical functioning with increasing age. They found no evidence of terminal drop.

Deeg and colleagues analyzed data for 88 residents of a home for the elderly in the Netherlands for whom four assessments were available in the year prior to death.[8] Declines were observed in physical, cognitive, and social functioning and morale as death was approached, and decedents had poorer scores in these domains than survivors. Model fitting revealed statistical evidence of an accelerated decline, or terminal drop, in physical functioning during this last year of life. In contrast to the present study, no age differences were found in physical functioning prior to death when comparing those younger than age 80 and those aged 80 and older. In another small study, there was no clear age gradient in the proportion of those judged clinically to be fully functional at 12 months, 6 months and 1 week before death.[15] These results suggest that there may be no age gradient in disability in the final year of life, but that this gradient may be present in the several years prior to death, as shown in this study. More research is necessary to answer this question definitively.

The current study has important implications for the older population now and in the future. Irrespective of the age at which an older individual dies, it is likely that a large proportion of the total years spent in the disabled state will be contributed by the years just prior to death. As the total population ages, preventive interventions, whether initiated at young or older ages, must have the ultimate goal of not only increasing longevity but of reducing disability. Any prevention efforts, at whatever age, to reduce total number of disabled person-years must address the issue of morbidity and disability prior to death, making this an important area for continued investigation. This study revealed that women decedents had proportionately higher rates of disability prior to death than men when compared to same-sex survivors, even after controlling for differences in age at death. This is important in an aging population in which, at each higher age, the female:male ratio increases and in which women have higher overall rates of disability than men.

Finally, the findings that the highest disability rates prior to death were found to be associated with death at the oldest ages can have grave implications for the total population burden of morbidity and disability in future years. If, as projected, life expectancy continues to increase,[16] the proportion of persons dying at the oldest ages will also increase. The total number of person-years of disability prior to death would thus increase, assuming age-specific rates of disability prior to death remain unchanged. Increased disability prior to death in future older populations, in which a large proportion of deaths will occur at the oldest ages, could make the quest for an overall compression of morbidity in the older population difficult, if not impossible. ☐

The Yield of Cholesterol Screening in an Urban Black Community

Nancy Knowles Russell, PhD, Diane M. Becker, ScD, MPH, Cheryl P. Finney, MPH, and Hamilton Moses, MD

ABSTRACT

Background: While the distribution of cholesterol levels have been well studied in the general population, little is known about cholesterol and other cardiovascular disease risk factors in screenings held in an urban Black community. This study was designed to determine the yield of cholesterol screening in this community.

Methods: Screening took place in eight community sites. Serum total cholesterol was measured using a rapid capillary technique. Blood pressure was taken according to national guidelines and the average of two to three measurements were used. Standard interviews were used to determine the presence of cardiovascular risk factors by history.

Results: Of the 562 individuals screened, 44.9 percent had cholesterol levels requiring referral for follow-up care. Of those with total cholesterol ≥6.21 mmol/L, 66.4 percent were previously undetected and more than half also had blood pressure levels ≥140/90 mmHg on screening; 45 percent of all participants had blood pressure ≥140/90 on screenings. Of those with a history of elevated total cholesterol levels, none had levels below 5.17 mmol/L at the time of screening.

Conclusions: Multiple risk factors are highly prevalent in the urban Black community during cholesterol screening programs. Findings suggest the need for cholesterol programs incorporating blood pressure screening in the urban Black community. (*Am J Public Health* 1991; 81:448–451)

Introduction

Recommendations by the National Cholesterol Education Program (NCEP) and the availability of portable rapid cholesterol analyzers have facilitated the implementation of population-based mass cholesterol screening programs.[1–6] Recent studies indicate that Blacks are less likely than Whites to participate in voluntary mass screening programs, often held in integrated shopping malls or work sites.[7] Little is known about blood cholesterol patterns or the potential yield of cholesterol screening programs targeted specifically to an urban Black population in settings that minimize volunteer-bias. This is of particular importance to public health given that cardiovascular disease and stroke remain the leading causes of morbidity and mortality in the Black population.[8,9]

This study was designed to determine the yield of cholesterol screening and the prevalence of other coronary heart disease (CHD) risk factors in an urban Black population in East Baltimore.

Methods

Data were obtained from the first six months (June 1988 through November 1988) of the East Baltimore Community Heart Disease Prevention Project, a free collaborative cardiovascular risk screening and education program conducted by The Johns Hopkins Hospital, the churches in East Baltimore, and the community Mayor's Stations. The program is available to 71,292 residents in the 21 census tracts constituting East Baltimore.[10] Residing in these census tracts are 47,438 adults ≥21 years of age; 88 percent are Black; 53 percent are female; the median age is 20.5 years; 57 percent are high school graduates; 46 percent have income levels below the poverty limit; 30 percent of eligible adults are unemployed.[10]

Screening sites included five churches, one public housing project, and two major grocery markets in the catchment area. Screening was concentrated in churches, as 68 percent of Blacks in East Baltimore are reported to be active members of a church.[10] To minimize bias that may be associated with purely voluntary attendance at sites dedicated solely to screening, church screenings took place in concert with high attendance Sunday services, while screenings in grocery stores concentrated on Friday evenings and Saturday mornings.

Serum total cholesterol (TC) was measured using a rapid capillary (fingerstick) method and the Reflotron technology (Boeringer-Mannheim, Indianapolis). Participants were not fasting. Standard procedures for quality control recommended by the Laboratory Standardization Panel of the NCEP were followed at each screening site.[11] In a recent companion study of over 9,000 screening participants using the same cholesterol screening technology and personnel used in this study, this method was 95 percent sensitive for identifying TC levels ≥5.17

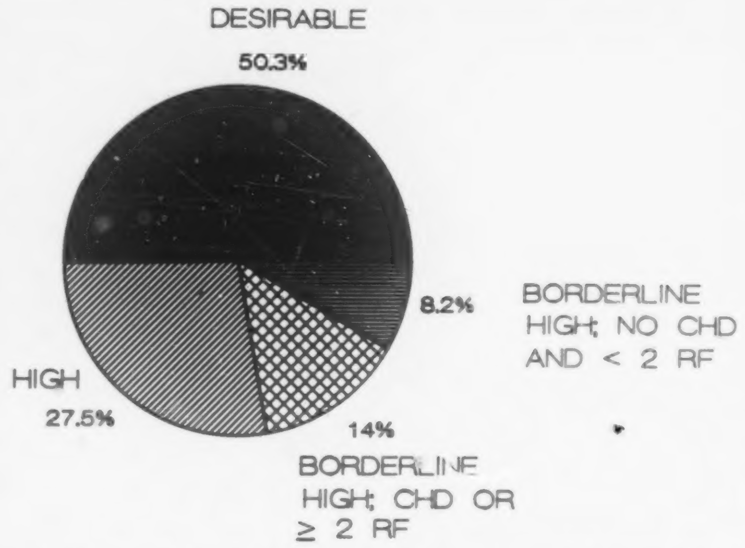

FIGURE 1—Overall Total Cholesterol Distribution according to National Cholesterol Education Program Adult Treatment Guidelines in Males (N = 186)

Borderline high = 5.17 to 6.18 mmol/L (200–239 mg/dl).
High = ≥6.21 mmol/L (240 mg/dl).
CHD = coronary heat disease.
RF = self-reported risk factors.

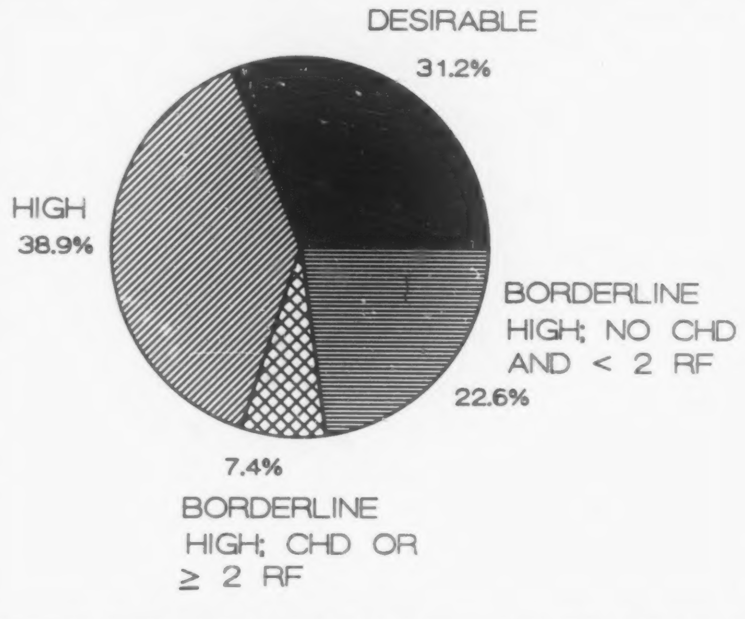

FIGURE 2—Overall Total Cholesterol Distribution according to National Cholesterol Education Program Adult Treatment Guidelines in Females (N = 366)

Borderline high = 5.17 to 6.18 mmol/L (200–239 mg/dl).
High = ≥6.21 mmol/L (240 mg/dl).
CHD = coronary heat disease.
RF = self-reported risk factors.

mmol/L (200 mg/dl), with the Johns Hopkins Lipid Research Clinics Laboratory method serving as the reference standard.[12]

Blood pressure measurements were taken with a mercury sphygmomanometer according to guidelines of the Joint Committee on High Blood Pressure IV (JNC IV).[13] The average of two measurements was used to characterize blood pressure during the screening for individuals with initial levels ≤120/80 mmHg; the average of three measurements was used for initial levels >120/80 mmHg.

Standardized personal interviews were conducted to determine the presence of CHD risk factors cited by the NCEP Adult Treatment Guidelines as factors that may lower the referral and treatment threshold for elevated cholesterol levels. Self-reported data were collected on age, height, body weight, smoking status, family history of premature CHD, medication use, and personal medical history of high cholesterol, hypertension, diabetes mellitus, CHD, and stroke. History of peripheral vascular disease proved difficult to assess by interview alone and was therefore not used. Accurate smoking history also proved difficult to obtain in the church setting, as many participating churches have explicit religious sanctions against smoking.

Results

The total number screened was 562; all were Black; the mean age was 50 ± 14.5 years for males and 51 ± 13.4 years for females; 66.7 percent were female; 11.8 percent had a personal history of CHD or stroke, and 10 percent had a history of diabetes. The mean TC was 5.35 ± 1.4[illegible] mmol/L for males and 5.86 ± 1.343 mmol/L for females. Among males, 41.5 percent had TC levels in the NCEP "high" and "borderline high" range with known CHD or two or more known risk factors (Figure 1). Among females, a total of 46.3 percent had TC levels classified as "high" and "borderline high" with existing CHD or two or more known risk factors (Figure 2). Thus, a total of 44.9 percent of all screening participants required referral to the medical care system for follow-up screening according to NCEP guidelines.

Data were also collected on prior awareness of cholesterol levels in 393 screening participants. The interview item on awareness was inadvertently omitted from printed instruments administered to the first 169 screenees, who did not differ

TABLE 1—Logistic Regression Analysis: Predictors of Total Cholesterol ≥6.21 mmol/L (N = 592)

Variable	Relative Odds	95% Confidence Interval:Odds
History of CHD or Stroke	1.17	1.01–1.35
Hypertension*	1.12	1.02–1.22
Female Gender	1.09	0.98–1.20
Age ≥60 years	1.05	0.38–1.15
History of Diabetes	1.03	0.90–1.18

*Hypertension = Blood pressure ≥140 mmHg or self-reported history of hypertension.

clinically or statistically in age, gender, TC levels, or co-morbidity from the next 393 participants. Of the 393 participants on whom the data were obtained, 56.3 percent reported never having had cholesterol levels checked before the screening. Of the 113 people identified as having TC levels ≥6.21 mmol/L on screening, 75 (66.4 percent) were not aware of high levels prior to the screening. More men (72 percent) than women (64 percent) were unaware of having elevated TC levels. Of those who reported having a known "high" TC level, 37 percent (23/61) had levels below 6.21 mmol/L at the time of this screening, but none were below 5.17 mmol/L; five people were taking a lipid-lowering medication.

More than half (54 percent) of those with TC levels ≥6.21 mmol/L also had hypertension, usually detected by screening rather than by history alone; 45 percent of screenees had blood pressure levels ≥140/90 mmHg on screening.

Logistic regression analysis was used to determine the relative importance of female gender, age ≥60 years, existing diabetes, a history of CHD or stroke, and the presence of hypertension in predicting "high" TC levels, ≥6.21 mmol/L (Table 1). Past history of CHD or stroke and hypertension, either by history or on screening, were the only principal independent predictors of having a "high" TC level. As body mass index (BMI) was calculated for only 126 participants, primarily because many individuals were reluctant to report weight or to be weighed in the mass screening setting, or did not know their height, this was not included in the overall regression analysis.

Discussion

Most prior screening studies conducted primarily in health care settings, work sites, and shopping centers in predominately White populations with a similar age distribution have yielded smaller percentages with NCEP "high" TC levels, generally in the 23 to 27 percent range[2,3,5,14] in contrast to the 35 percent found in the urban Black population in this study. However, in the second National Health and Nutrition Examination Survey (NHANES II) of a national probability sample of the civilian noninstitutionalized US population, a smaller percentage of Blacks (24 percent) were found to have NCEP "high" TC levels.[15] Furthermore, Whites were found to be more likely to have "high" or "borderline high" TC levels. This seeming discrepancy between the NHANES data and results of our study may be explained by the probable lower socioeconomic distribution of the community represented here.

Potential biases in the ascertainment of TC levels and subsequent NCEP classification may have resulted in underestimating the number of screening participants requiring referral to the medical care system. Specifically, we were unable to obtain accurate information for all individuals on smoking, obesity, and peripheral vascular disease in the screening settings. It is possible that larger numbers of individuals with "borderline high" TC levels had two or more NCEP-defined cardiovascular risk factors; this would place them at higher CHD risk and result in a medical care referral. Conversely, other biases in the sample may have resulted in overestimating the numbers requiring referral. Namely, women were differentially represented among participants. False positive misclassification bias may potentially have occurred in the studied population because women and Blacks are known to have higher levels of high density lipoprotein cholesterol, the lipoprotein subfraction that is potentially protective and that contributes to the total cholesterol level.[16] This potential source of bias may exist in this study as more women than men had "high" TC levels and slightly more women than men had levels that required referral to the medical care system according to NCEP Guidelines.

The association between hypertension and high cholesterol levels found in this study has also been reported recently in other population-based studies in Whites.[17] This link is of particular concern in the Black community given the known high prevalence of hypertension. Although the mechanism of this clustering of high cholesterol levels and high levels of blood pressure is not clear, replications of this finding suggest that the coexistence is not coincidental. The confluence of older age, diabetes, obesity, high sodium and fat diets, and sedentary life-style in urban Blacks may be important in the development of both hypertension and hypercholesterolemia.

This study, perhaps because of the nature of its venues, showed that women and older people were more likely to come to be screened. Cholesterol screening targeted specifically to Blacks in East Baltimore yielded a large number of people with previously undetected high cholesterol levels as well as large numbers of people with co-existing hypertension and hypercholesterolemia. These findings suggest the need for screening programs that address multiple rather than single risk factors in the Black community. Outreach strategies that extend beyond churches and food stores may be required to access men and younger people in urban Black community settings. In order to fulfill their ultimate mission to lower cardiovascular disease risk, cholesterol screening programs may need to focus strongly on the provision of health care follow-up, given the known dearth of chronic disease prevention services in inner-city Black communities.[18] Further, Blacks are known to utilize the health care system in unique ways that do not enable implementation of traditional health education or health promotion efforts.[19,20] Investigations of innovative programs that offer intensified on-site diet counseling and that provide at least first-stage verification of initial elevations of cholesterol may assist in diminishing referrals to the overburdened medical care systems in these communities.[19] ☐

Call for Papers on Quality of Nursing Life: Taking Charge of Change

The Alberta Hospital Association, in cooperation with a number of nursing service, nursing education, professional, paraprofessional, employer, and labor organizations is sponsoring its second biannual forum in February 1992.

Quality Of Nursing Life: Taking Charge of Change is the theme of the forum to be held in Calgary, Alberta, Canada, February 5–7. The focus of the forum is to share innovative ideas for taking a leadership role in changes in health care.

Papers are being sought that present proven innovative ideas related to advancing positive change, including participation in decision making, dealing with the impact of economics, professional responsibility and ethics, promoting wellness for nurses, innovations in education, living with new information systems, promoting professional pride, or expanding roles of nurses.

A package providing details of abstract requirements is available from Education Services, Alberta Hospital Association, 10009-108 Street, Edmonton, Alberta, Canada T5J 3C5; (403) 498-8403, FAX (403) 498-8465. Deadline for receipt of abstracts is May 1.

Alcohol Drinking Patterns and Blood Pressure

Marcia Russell, PhD, M. Lynne Cooper, PhD, Michael R. Frone, PhD, and John W. Welte, PhD

ABSTRACT

Background: **Although blood pressure tends to increase with average alcohol consumption, little is known about the effects of drinking patterns on blood pressure. Therefore, the effects of average drinks per day and drinking pattern (defined as the independent and interactive effects of quantity and frequency) on blood pressure were compared.**

Methods: **Data were obtained from a random sample survey of 1,635 household residents in Erie County, New York. Alcohol-blood pressure relationships were examined using multiple regression analyses that controlled for the potentially confounding influence of 13 additional risk factors for elevated blood pressure.**

Results: **Consistent with prior research, a positive relationship was found between average drinks per day and diastolic and systolic blood pressure. Analyses examining the effect of drinking pattern indicated that drinking frequency had a positive effect on both diastolic and systolic blood pressure, whereas drinking quantity did not affect either. Furthermore, there was little evidence that the frequency-by-quantity interaction affected blood pressure.**

Conclusions: **Low average alcohol intake and low blood pressure were associated with infrequent drinking, rather than with frequent drinking of small amounts of alcohol. Results suggest that the standard practice of averaging alcohol consumption may obscure important effects of drinking frequency on health. (*Am J Public Health* 1991;81:452–457)**

Introduction

Despite the well documented relationship between average alcohol intake and elevated blood pressure,[1,2] we know relatively little about the effects of drinking patterns on blood pressure, where patterns are defined in terms of specific combinations of quantity drunk per drinking day and frequency of drinking days. Prior research has typically combined quantity and frequency measures of alcohol intake and expressed this information in terms of average consumption (average drinks per day, per week, or per month). However, such averaging may obscure potentially important differences in blood pressure associated with different drinking patterns. For example, although a person who drinks only two drinks every day of the week and one who has 14 drinks on Saturday night both average two drinks a day, blood pressures associated with these two patterns may not be the same.

To investigate the role of drinking pattern in the relationship of alcohol consumption and blood pressure, we examined the relationship between discrete combinations of quantity and frequency of drinking and average drinks per day; determined the effect of average drinks per day on blood pressure; determined the effect of drinking pattern on blood pressure by analyzing the independent and interactive effects of alcohol quantity and frequency; and contrasted the effects of drinking pattern and average drinks per day on blood pressure.

Methods

Sample

Data for the present analyses came from a representative adult household survey of stress, alcohol use, and hypertension conducted in Erie County, New York (N = 1,933). Respondents were identified using a stratified, three-stage probability sampling procedure designed to yield approximately equal numbers of Blacks and all others at three levels of education (less than high school, high school, at least some college). The first stage of sampling was the selection of US census blocks, stratified by race and education, and selected with probabilities proportional to size. In the second stage, housing units were selected with probabilities inversely proportional to the first stage selection probabilities. Finally, one adult (at least 19 years of age) was randomly selected from each household.

The overall sample completion rate was 78.3 percent, with the majority (84.5 percent) of noncompletions due to refusals. To provide population estimates in the present study, the sample was: poststratified by race, education, and sex (females were unintentionally oversampled) to match proportions reported in the 1980 census for Erie County; and weighted by the individual probability of selection.

Present analyses were conducted on a subset of 1,725 (weighted N = 1,630) respondents. Respondents over age 74 were eliminated (N = 75) because few drank alcohol, blood pressure measurements were missing for many, and doing so made our data more comparable to other studies of alcohol and hypertension. An additional 133 respondents who were

missing one or more of the study variables were deleted in order to ensure comparability across analyses. After exclusions, the weighted sample was 91 percent White, 54 percent female, and 63 percent married; 70 percent had completed at least a high school education. Mean age was 45 years (SD = 16.5). Forty-eight percent of the sample was working; of these, 51 percent held white collar jobs.

Procedures

Data were collected by a corps of 27 interviewers in the summer and fall of 1986. Interviewers received five days of intensive training on general and survey-specific interviewing techniques and three days of training on physical measurements, including blood pressure measurement. Interviews were conducted in respondents' homes using a highly structured interview schedule that included diet, smoking, and physical activity as well as medical history. The entire procedure took about 90 minutes; respondents were paid $25.

Measures

Blood Pressure: Standardized procedures using the American Heart Association protocol were used to measure systolic and diastolic blood pressures (SBP and DBP, respectively).[3] Blood pressure was assessed using mercury sphygmomanometers (Baumanometer, Model 300) calibrated for accuracy on a weekly basis. Respondents were asked not to drink alcohol during the interview. Properly fitted cuffs were placed on the right arm approximately 15 minutes before the end of the interview; respondents were asked to refrain from smoking, drinking coffee, or moving around the room until after their blood pressures were taken. Readings were made to the nearest 2 mmHg, and DBP was taken at the fifth Korotkoff phase (i.e., cessation of pulse sounds). Mean measures of SBP and DBP based on the last two of three readings were utilized in all analyses.

Alcohol Measures: Alcohol measures were adapted from the National Health and Leisure Time Survey.[4] Standard quantity and frequency questions (see Appendix) were asked on usual drinking during the past year. Average drinks per day was calculated by multiplying frequency of drinking by the number of drinks consumed on a typical day and dividing by 365. Quantity (number of drinks consumed on a typical drinking day—drinks per drinking day) was categorized as one or two drinks, three or four drinks, or five or more. Frequency (drinking days during the past year) was also categorized to yield groups of respondents who drank daily or almost daily, one to four times weekly, or less-than-weekly.

Nine drinking patterns were constructed by cross-tabulating the above quantity and frequency categories. They ranged from less-than-weekly drinkers who usually had one or two drinks per drinking day to those who drank daily or almost daily and usually had five or more drinks.

Covariates: The following potentially confounding factors were statistically controlled in all analyses: age (in years); race (1 = other than Black, 2 = Black); sex (1 = male, 2 = female); body mass index (weight in kg/height in meters, squared); marital status (0 = not married, 1 = married/living as married); education (in years); sodium intake (frequency of using salt at the table, in cooking, and eating salty snacks); calcium intake (milligrams per day based on the frequency of consuming calcium-rich foods, calcium supplements, and calcium-containing antacids); current cigarette use (number of cigarettes smoked per day); and two indices of frequency of physical activity.[5]

Also included as covariates were measures of family history of hypertension, self-reported hypertensive status, and whether or not antihypertensive medication was taken in the 24 hours prior to blood pressure measurement. Because a number of respondents were missing information on family history, two dummy variables were constructed, one to represent information concerning a positive family history of hypertension (family history: positive, coded as 0 = no, 1 = yes), and the other to represent missing information (family history: missing, coded as 0 = no, 1 = yes). Similarly, two dummy variables were used to represent information concerning respondents' self-report of their hypertensive status and current use of antihypertensive medication. The first (hypertension: no medication, coded as 0 = no, 1 = yes) represents individuals who reported that they had been told by a doctor or other health professional that they were hypertensive, but had not taken antihypertensive medication during the past 24 hours. The second dummy variable (hypertension: medication, coded as 0 = no, 1 = yes) represents individuals who reported that they were hypertensive and that they had taken antihypertensive medication during the past 24 hours.

Statistical Analysis

Three sets of statistical analyses were conducted. First, multiple regression was used to examine the relationship of average drinks per day to SBP and DBP, while controlling for covariates.[6]

Second, hierarchical multiple regression analysis was used to examine the independent and interactive effects of frequency and quantity on blood pressure.[6,7] More specifically, the hierarchical regression analysis proceeded in the following manner for both SBP and DBP: a block of covariates was first added to the regression equation in Step 1, followed by continuous measures of frequency and quantity in Step 2, which was followed by the interaction between frequency and quantity in Step 3. These hierarchical regression analyses did not contain abstainers because their inclusion would have led to an unbalanced design (i.e., a design with empty cells);[8] abstainers' scores on the quantity and frequency measures were both fixed at zero. Thus, respondents (i.e., abstainers) who had a zero on frequency could only have a zero on quantity, and vice versa. When a two-factor design is unbalanced, it is inappropriate to test for an interaction among its factors.[8] However, a two-way interaction can be tested if the design can be balanced by removing one or more levels of one or more factors.[8] In the present case, a balanced design was achieved by removing abstainers (i.e., the levels that represented zero frequency and zero quantity). Thus, we tested for a quantity-by-frequency interaction among drinkers only.

Third, to compare adjusted blood pressures in the nine drinking pattern groups with those of abstainers, we conducted two dummy variable regression analyses.[6] In each analysis, we examined the relationship of nine dummy variables to either SBP or DBP, while controlling for the covariates. Each dummy variable represented one of the nine drinking patterns with abstainers serving as the reference category. Therefore, in each regression equation, the unstandardized regression coefficient for a given dummy variable represented the mean difference in adjusted blood pressure for a specific drinking pattern compared to abstainers, and the constant represented the average adjusted blood pressure for abstainers.

As noted earlier, data were weighted to adjust means and regression coefficients for the complex survey design. However, standard errors have not been

adjusted for design effects because the requisite statistical programs to do so were not available to us.

Results

Drinking Pattern

Mean values for average drinks per day associated with each pattern are presented in Table 1. As expected, marginal values for average drinks per day increased both as the frequency of drinking increased (r = .64) and as the usual quantity consumed on a typical drinking day increased (r = .56). Heavy drinking was more prevalent among daily drinkers than among those who drank less frequently. However, the magnitude of the relationship among drinkers is relatively modest (r = .23), which provides further justification for analyzing the independent and interactive effects of quantity and frequency on blood pressure.

Although quantity definitely influences average drinks per day, given the distribution of drinking in this household sample, frequency seems to play a more important role than quantity in determining which drinking patterns are associated with lower mean values of average drinks per day and which are associated with higher values. For example, mean averages of one drink or more per day were associated with moderate and heavy weekly drinking, and with daily drinking, irrespective of quantity; averages of less than one drink per day were associated with light, weekly drinking and less-than-weekly drinking, irrespective of quantity.

The most prevalent drinking patterns, accounting for 43 percent of the population, were characterized by light drinking less-than-weekly or weekly, both of which were associated with low average drinks per day. In contrast, only 8 percent of the population drank as often as daily or nearly every day.

Blood Pressure

Results of the multiple regression equations predicting SBP and DBP from average drinks per day are summarized in Table 2. Blood pressure had the expected relation to all covariates except race and sodium intake. Failure to observe higher average blood pressures among Blacks than Whites reflects their relatively small weighted numbers in these population-based analyses. Unweighted analyses are planned to investigate racial differences in the relation of blood pressure to drinking patterns. The negative relation of blood pressure to sodium intake reflects the lower discretionary salt intakes among individuals who had been told they were hypertensive, presumably in response to medical advice.

After covariates were taken into consideration, average drinks per day made a statistically significant contribution to the prediction of both SBP and DBP. The b values indicate that SBP was elevated an average of 1.21 mmHg, and DBP was elevated an average of 0.55 mmHg, for every increment of one drink in average drinks per day.

Drinking Pattern and Blood Pressure

Systolic Blood Pressure: The hierarchical regression analysis examining the independent and interactive effect of quantity and frequency on SBP revealed a significant positive relationship between frequency and SBP, but no significant effect for quantity and no significant quantity-by-frequency interaction (Table 3). The b value for frequency of drinking days during the past year indicated that SBP increased .021 mmHg with every additional day of drinking. Thus, SBP would be an average of 6.6 mmHg higher among those who drank daily than among those who drank only once a week (365 − 52 = 313 × .021 mmHg per drinking day per year = 6.6 mmHg).

*Abstainers omitted.

**Regression coefficients were taken from the step at which they were entered; therefore, each coefficient is controlled for all other variables entered at the same step and prior steps.

The dummy variable regression analysis comparing SBP among abstainers and drinkers found that compared to abstainers, mean SBP was significantly higher among light daily, moderate weekly, moderate daily, or heavy weekly drinkers (Table 4). These results paralleled the hierarchical regression results, indicating that relative to abstention, more frequent drinking was associated with increased SBP within each quantity category, whereas a tendency for SBP to increase with quantity was observed only among weekly drinkers.

Diastolic Blood Pressure: Overall, the main effects of the hierarchical regression analysis examining the independent and interactive effect of quantity and frequency on DBP were similar to those observed for SBP (Table 3). The b value for frequency indicated that DBP increased .015 mmHg with every additional day of drinking. Thus, DBP would be approximately 4.7 mmHg higher among daily drinkers compared to the individual who drank once a week.

In addition, there was a quantity-by-frequency interaction (Table 3). We explored the nature of the interaction by analyzing the effect of frequency among light, moderate, and heavy drinkers, and the effect of quantity among less-than-weekly, weekly, and daily drinkers. This set of follow-up analyses, however, failed to uncover a strong, readily interpretable, functional form for the quantity-by-frequency interaction. The fact that this interaction was weak and failed to replicate with systolic blood pressure indicates that it may be a chance finding.

The dummy variable regression analysis comparing DBP among abstainers and drinkers found that, compared to abstainers, mean DBP was significantly higher among light weekly, light daily, or moderate daily drinkers (Table 4). Again, these results supported the hierarchical regression results by indicating that relative to abstention, more frequent drinking increased DBP at every level of quantity, but that higher quantity did not increase DBP within the frequency categories.

Discussion

To summarize, our analyses revealed a significant increase in blood pressure, particularly SBP, with increasing average drinks per day. However, consideration of drinking patterns indicated that, among drinkers, this increase was influenced more by the frequency of drinking than by the quantity of alcohol consumed. Although a quantity-by-frequency interaction was observed for DBP, it was not observed for SBP, and its pattern had no ready explanation. Finally, relative to abstainers, respondents who drank less often than weekly tended to have lower blood pressures, and those who drank weekly or more often tended to have higher blood pressures.

As reviewed by Gleiberman and Harburg,[9] a number of epidemiological studies have reported that individuals having relatively low average alcohol intakes tend to have lower mean blood pressures than abstainers, exhibiting a U- or J-shaped alcohol-blood pressure relation. Although not statistically significant, this tendency was also observed in the present study, as indicated by the fact that blood pressure among abstainers tended to be higher than that among less-than-weekly drinkers, who had low average drinks per day. Studies are needed to determine whether very light or occasional alcohol use exerts a physiological protective effect or if it is associated with psychological or behavioral correlates related to lower blood pressure.[9]

Methods employed to measure and analyze alcohol-blood pressure relationships may influence its interpretation. Studies in alcoholic men[10] and pregnant women[11] found that self-reported frequency was more reliable than self-reported quantity. Thus, lower reliability may have contributed to our failure to observe a significant effect of quantity on blood pressure in the present study. Also, it is important to note that the prepotency of frequency in the relationship between alcohol use and blood pressure is obscured by employing measures of average alcohol intake. Analyses of drinking pattern, in which the independent and interactive effects of quantity and frequency are taken into consideration, clearly indicate that drinking patterns characterized by infrequent drinking are associated both with low blood pressures and relatively low average drinks per day. Conversely, daily drinking is associated both with high blood pressures and relatively high average drinks per day.

Data from the 1979 National Survey of US drinking practices indicate that light, daily drinking was reported by only 2 percent of the US population,[12] suggesting that relatively few people who report low average drinks per day are light, daily drinkers. Therefore, it may be misleading to attribute purported health benefits as-

Heavy, Less-Than-Weekly	−3.50	2.35	−1.47	1.54
Heavy, Weekly	5.16	1.82	.81	1.19
Heavy, Daily	5.07	2.99	2.87	1.95
Constant (Abstainers)*	108.45	4.20	72.33	2.74

*Because abstainers served as the reference category, the constant represents the adjusted blood pressure for abstainers. The b weights for each drinking pattern (e.g., light, less-than-weekly) represent the magnitude of the difference in blood pressure for the drinking pattern compared to abstainers. Thus, the adjusted blood pressure for each drinking category is equal to the sum of the constant and its b weight.

sociated with low average drinks per day to light, daily drinking.

We believe that recognition of the importance of drinking frequency in determining the effects associated with average drinks per day is important for public health policy. The relatively low correlation between quantity and frequency among drinkers and the fact that few people in the US drink daily,[12] suggests that average drinks per day does not adequately represent actual drinking practices in the US. Accordingly, findings of health risks or benefits based on analyses employing average drinks per day cannot be translated directly into public health policy. The present data suggest that previously reported health benefits associated with low average drinks per day[2,9] are likely to be related to light, weekly drinking and infrequent drinking, rather than to light, daily drinking.

This is the first time that elevations in blood pressure have been attributed to drinking frequency, even in light drinkers, and it is important that these analyses be replicated. Assuming for the moment that they prove to be reliable, it is interesting to speculate about how frequent drinking might influence blood pressure. It has been hypothesized that individuals who recently drank alcohol may have elevated blood pressure because they are experiencing mild withdrawal symptoms or direct pressor effects of alcohol.[2] If this is so, it may be that individuals in our sample who reported drinking daily or nearly every day were more likely to be undergoing these effects. Criqui, *et al,*[13] have noted that repeated acute elevations in blood pressure related to frequent alcohol use are functionally equivalent to a chronic condition. Thus, elevations in blood pressure related to daily drinking could have significant implications for cardiovascular health and should not be dismissed as a short-term phenomenon.

Mean SBP was 6.6 mmHg higher and DBP was 4.7 mmHg higher among daily drinkers than among individuals who drank only once a week. Blood pressure elevations of this magnitude have both clinical and population significance. The association of DBP with stroke and with coronary heart disease (CHD) was recently investigated in nine major prospective observational studies, correcting for risk underestimates in previous reports related to "regression dilution" bias.[14] It was found that a long-term difference of 5–6 mmHg in usual DBP was associated with about 35–40 percent less stroke and 20–25 percent less CHD.[14] Data from the Multiple Risk Factor Intervention Trial[15] indicate that SBP is more strongly associated with CHD death than DBP, suggesting that the effect of frequent drinking on SBP may represent a greater CHD risk than is indicated by its effect on DBP.

The potential effect on health of relatively small reductions in mean blood pressure is illustrated by an overview of unconfounded randomized trials of antihypertensive drugs.[16] In 14 such trials, the mean treatment duration was five years, lowering mean DBP 5–6 mmHg; stroke was reduced by 46 percent, and CHD was reduced by 14 percent.

Within the DBP range covered by prospective observational studies (about 70–100 mmHg), there was no evidence of any "threshold" below which lower levels of DBP were not associated with lower risks of stroke and of CHD. Although increased risk may be small at lower DBP levels, the net effect is substantial when aggregated over the large numbers of people affected. Also, there are large numbers of individuals with moderately elevated blood pressures among whom relatively small increases might result in levels associated with diagnosed hypertension.

In sum, the effect of alcohol consumption on blood pressure has public health as well as clinical relevance. The present study illustrates how the standard practice of averaging alcohol consumption may obscure important effects of drinking pattern on health, and it is important that the study be replicated to determine the reliability of its findings. These results suggest that it may be useful to examine the independent and interactive effects of drinking quantity and frequency on other conditions thought to be influenced by alcohol intake, as well as in future epidemiologic studies of the alcohol-blood pressure relationship. ☐

APPENDIX

Frequency: **Thinking back over the past 12 months, how often did you drink any kind of alcoholic beverage, that is, beer, wine, and liquor? Asked only of people who had reported drinking during the past year, respondents chose from eight categories: every day; almost every day; three or four times a week; two times a week; once a week; two or three times a month; once a month; or less than once a month.**

Quantity: **During the past 12 months, about how many drinks, on the average, would you have on a typical day when you drank? A drink is a 4 oz glass of wine, a 12 oz beer, or a drink containing 1 oz of liquor. Responses were open-ended.**

Caffeine Consumption During Pregnancy and Fetal Growth

Laura Fenster, PhD, Brenda Eskenazi, PhD, Gayle C. Windham, PhD, and Shanna H. Swan, PhD

ABSTRACT

Background: The purpose of this study was to examine the association between maternal caffeine consumption and low birthweight, intrauterine growth retardation, and prematurity, adjusting for multiple confounders.

Methods: Data obtained from birth certificates and interviews on 1,230 women with singleton live births were analyzed to evaluate the potential influence of caffeine consumption during the first trimester on fetal growth.

Results: The crude odds ratio for intrauterine growth retardation in infants of women reporting heavy caffeine consumption (>300 mg/day) was 3.86 (95% CI = 1.80, 8.40) which decreased to 2.90 (95% CI = 1.23, 6.87) after controlling for confounding factors. The adjusted odds ratio for low birthweight and heavy maternal caffeine consumption was also elevated (OR = 2.05; 95% CI = 0.86, 4.88). Women who reduced their caffeine intake from greater than 300 mg/day to less than that early in pregnancy had lower risks of delivering infants with either intrauterine growth retardation or low birthweight than women who continued to consume that amount. Preterm delivery appeared to be unrelated to caffeine consumption.

Conclusions: Taken together with studies reporting similar findings, these results suggest that heavy caffeine consumption increases the risk for fetal growth retardation. (*Am J Public Health* 1991;81:458–461)

Introduction

In 1980, the United States Food and Drug Administration warned pregnant women to restrict their intake of caffeine based on increased adverse reproductive outcomes in animals.[1] Since then, a number of epidemiologic studies have examined the association between caffeine intake and low birthweight (LBW) and a few have investigated its relationship to intrauterine growth retardation (IUGR). In a prospective study, Martin and Bracken found a more than two-fold risk of LBW in term deliveries associated with caffeine intake of 151–300 mg daily during the first trimester and a greater than four-fold risk associated with intake of >300 mg daily.[2] A case-control study which combined cases of LBW and IUGR found an increased risk associated with caffeine intake greater than 300 mg daily during the first trimester (OR = 2.94; 95% CI = 0.89, 9.65).[3] In addition, a retrospective study demonstrated a relationship between caffeine consumption of greater than 300 mg daily and reduced birthweight.[4] In contrast, a prospective[5] and a large retrospective[6] study found no relationship between caffeine or coffee consumption and reduced birthweight, respectively.

Methods

Participants and Questionnaires

Participants were women selected as controls in a case-control study of spontaneous abortion (SAB); a detailed description of subject selection and recruitment is presented elsewhere.[7] Birthweight was obtained from birth certificates. LBW was defined as birthweight less than 2,500 grams. Gestational age was calculated from the date of the last menstrual period (LMP) to the baby's birth date, as reported on interview. IUGR was defined as weight less than the tenth percentile of the mean weight at each gestational week using standards developed for California (all races and sexes combined).[8] Preterm delivery was defined as gestational age of less than 37 weeks.

The interview was conducted by telephone, on average, nine months after birth. For caffeinated beverage consumption questions (caffeinated coffee, tea and soft drinks), the participant was asked the amount consumed during the month before pregnancy, if it changed during pregnancy and, if so, when and to what amount. This information was used to calculate each participant's average consumption during the first trimester of pregnancy, based on her consumption each week. Caffeine consumption was calculated by summing the average amount of caffeinated coffee, tea, and soft drinks consumed, assuming a caffeine content of 107 mg/cup, 34 mg/cup, and 47 mg/can, respectively.[9]

The analyses were limited to singleton births (n = 1,252). Women who were missing information on birthweight (n = 1) or on caffeine consumption (n = 8) or whose calculated gestational age was 45 weeks or more (n = 13) were excluded from the analyses, leaving 1,230 singleton live births.

From the Reproductive Epidemiology Program, California Department of Health Services, Berkeley (Fenster, Windham, Swan); and the Departments of Maternal and Child Health and Epidemiology, University of California School of Public Health, Berkeley (Eskenazi). This paper, submitted to the Journal March 19, 1990, was revised and accepted for publication October 10, 1990.

Statistical Analyses

We examined maternal characteristics within four categories of caffeine consumption consistent with those from previous studies:[2–4] no caffeine; average caffeine use of 1–150 mg/day (light use); 151–300 mg/day (moderate use); and >300 per/day (heavy use). Analysis of variance was used to determine whether mean birthweights or mean gestational ages differed by category of caffeine use. Unadjusted odds ratios (OR), confidence intervals (CI) and chi-square trend tests were calculated for three levels of caffeine consumption with no consumption as the reference group.

Adjusted odds ratios were calculated using logistic regression with indicator variables for light, moderate, and heavy caffeine use. Caffeine was also modeled as a continuous variable. Since results were similar, categorical variables are presented for ease of comparison to other studies.

Confounding variables were included if they were strongly related to LBW or related to both LBW and caffeine use. The following maternal characteristics were entered into the LBW models: maternal age (≤ 34, >34); parity (0, ≥ 1); race (White, Hispanic, other); hypertension during pregnancy (yes, no); cigarettes smoked (0, 1–10 daily, ≥ 11 daily); and alcohol consumed (0, 1–3 drinks per week, ≥ 4 drinks per week). Separate models were run to test for an interaction between caffeine and tobacco use and between caffeine and alcohol consumption.

Reductions in caffeine consumption early in pregnancy were examined to determine whether these changes might affect fetal growth. Crude and adjusted odds ratios were calculated separately for women who did and did not reduce their intake from greater than an average of 300 mg/day to less than that amount within six weeks of their LMP. The reference group for these analyses was women with no caffeine consumption. Six weeks post-LMP was chosen as the time to evaluate the effect of reducing caffeine consumption because it approximates the earliest time that a woman realizes she is pregnant.

The strategy outlined above was followed for the univariate and multivariate analyses of caffeine consumption and IUGR or prematurity. The following covariates were entered in the models for IUGR: hypertension, cigarettes, and alcohol, as defined above. Variables included in the models for prematurity were: education (less than high school, high school graduate, some college, college graduate), race, hypertension, cigarettes and alcohol.

Results

Characteristics of Study Population

Table 1 presents population characteristics by four categories of caffeine consumption. The following variables were associated with increased caffeine consumption: multiparity, one or more therapeutic abortions, being employed, and use of cigarettes or alcohol. Ethnicity other than White or Hispanic was associated with decreased caffeine consumption, as was being more highly educated.

Association with LBW, IUGR

Overall, the risk factors for LBW were consistent with previous studies.[10] Nulliparous women over 34 years of age were at increased risk for delivering a LBW infant. Prior stillbirth, hypertension during the current pregnancy, smoking more than 10 cigarettes per day, or drinking four or more alcoholic drinks each week were associated with LBW. Race was also associated with LBW; Whites were least likely to deliver a LBW infant. Women who did not have insurance coverage for prenatal care (a surrogate measure for low socioeconomic status) were also at increased risk for LBW. IUGR was more common among women with hypertension during pregnancy, smoking more than 10 cigarettes per day, or drinking four or more alcoholic drinks per week.

Association of LBW and Caffeine

The mean birthweights for no, light, moderate, and heavy caffeine use were 3327 grams, 3311 grams, 3288 grams and 3170 grams respectively. Table 2 presents the unadjusted and adjusted odds ratios for LBW by caffeine consumption. A dose-response effect with increasing consumption of caffeine was observed (χ^2 trend = 4.03, p = 0.05). The crude risk for those with the heaviest level of caffeine consumption was twice that in the unexposed group. Adjusting for covariates resulted in a slightly lowered measure of association. Including interaction terms for cigarette smoking and caffeine consumption and for alcohol and caffeine consumption did not alter these estimates. Women who reduced their heavy caffeine consumption (within six weeks of their LMP) had a lower risk of delivering a LBW infant (adjusted OR = 0.65; 95% CI = 0.20, 2.11) than those women who continued to drink this amount (adjusted OR = 3.05; 95% CI = 1.09, 8.51).

Association of IUGR and Caffeine

The association of caffeine and IUGR increased with amount (χ^2 trend = 11.42, p = 0.0007), with a doubled risk for medium consumers and almost a four-fold risk for heavy consumers (Table 3). The adjusted OR for heavy caffeine consumption remained elevated, although decreased (OR = 2.90). Addition of interaction terms for cigarette smoking and caffeine consumption and for alcohol and caffeine consumption did not alter these estimates. Women who reduced their heavy caffeine consumption had a lower risk of IUGR (adjusted OR = 1.58; 95% CI = 0.56, 4.42) than women who continued this level of caffeine intake (adjusted OR = 3.74; 95% CI = 1.34, 10.41).

Association of Preterm Delivery and Caffeine

Mean gestational age varied little by caffeine use. Although the crude odds ratio for preterm delivery and heavy caffeine consumption was somewhat elevated (OR = 1.76), this estimate was decreased after multivariate adjustment (adjusted OR = 1.31; 95% CI = 0.63, 2.69). Women who continued their heavy caffeine consumption had a higher risk of preterm delivery (adjusted OR = 1.72; 95% CI = 0.70, 4.24) than women who reduced their intake (adjusted OR = 1.10; 95% CI = 0.50, 2.43).

Discussion

This study indicated elevated risks for IUGR and for LBW associated with heavy caffeine consumption which continued beyond the sixth week of pregnancy. Recall bias is an unlikely explanation of these findings since little relationship between preterm delivery and caffeine consumption was seen. Consistency of reporting of caffeinated beverage consumption was examined in a smaller case-control study of SAB,[11] in which caffeine consumption was asked as in this study. Substantial agreement for reports of caffeine consumption between interviews which were six months apart was found; approximately 77 percent of women's responses agreed to within one cup.[11] In addition, reporting of coffee consumption has recently been shown to have good reliability over a period of time which ranged from nine days to 6.5 years.[12]

*Numbers for some variables do not total 1,230 because of missing data. Percentages for some variables do not total 100 because of rounding errors.

In these analyses, pre-pregnancy weight and pregnancy weight gain—maternal characteristics known to be associated with fetal growth—were not collected.[10] In Martin and Bracken's study, although caffeine users tended to gain less weight than nonusers, the caffeine risk estimates were only slightly reduced when weight gain was entered into the logistic models.[2] Birthweight and IUGR may also be influenced by exposures occurring during the second and third trimesters which were not ascertained. However, a case-control study found that average coffee and tea consumption in the second and third trimesters did not differ appreciably from that in the first trimester.[13]

There are two potential sources of exposure misclassification. We did not collect information on caffeine intake from caffeinated drug use, chocolate, or cocoa. This bias is unlikely to be substantial since for most pregnant women the largest source of caffeine intake is coffee.[4,14] Nevertheless, our measures of caffeine consumption were crude, given the substantial variation in caffeine content with method of beverage preparation and volume of serving.[9]

Our results suggest an effect of caffeine consumption of greater than 300 mg/daily on IUGR and LBW but not preterm delivery. These findings are consis-

tent with those of other studies[2–4] and are biologically plausible. Caffeine is readily absorbed from the digestive tract and freely crosses the placenta.[15,16] Caffeine increases intercellular cyclic 3′,5′-adenosine monophosphate (cyclic AMP), which may directly interfere with fetal development.[17] A dose of 200 mg of caffeine significantly decreases blood flow in placental villi,[18] probably through vasoconstriction.[19] Any reduction in uteroplacental circulation is strongly associated with decreased fetal growth.[10] IUGR[20] and LBW[10] are associated with increased risks of perinatal mortality and morbidity. Clinicians should counsel women early in pregnancy about reducing caffeine intake to below 300 mg daily. ☐

Does Increased Detection Account for the Rising Incidence of Breast Cancer?

Jonathan M. Liff, PhD, John F. C. Sung, PhD, Wong-Ho Chow, PhD, Raymond S. Greenberg, MD, PhD, and W. Dana Flanders, MD, DSc

ABSTRACT

Background: The incidence of breast cancer has been increasing over time in the United States.

Methods: To determine the role of screening in this increase, trends in the incidence of *in situ* and invasive carcinoma of the breast were evaluated using records of the metropolitan Atlanta SEER program between 1979 and 1986. From a sample of records, evidence of symptoms and mammographic screening prior to diagnosis was recorded.

Results: The average annual age-adjusted incidence of invasive disease rose 29 percent among Whites and 41 percent among Blacks. Incidence increased in all age groups. A trend towards earlier detection of invasive disease was found. Asymptomatic tumors accounted for only 40 percent of the increased incidence among whites and 25 percent of the increased incidence among blacks, with mammography as the principal contributing procedure.

Conclusions: These data suggest that increased detection accounts for some but not all of the rising incidence of breast cancer in the United States. (*Am J Public Health* 1991;81:462–465)

Introduction

A rise in the incidence of breast cancer has been observed in the United States during the past decade.[1-5] In part, this phenomenon may be attributable to the increasing prevalence of suspected risk factors.[6-11] Alternatively, increased mammographic screening[12,13] could have resulted in more complete recognition of disease. This study was undertaken to determine whether the trends in breast cancer incidence could be explained by increased screening.

Methods

Data for this study were collected by a population-based cancer registry that has been described elsewhere.[14] Briefly, clinical and demographic data are collected on all new cases of cancer diagnosed among residents of five counties in metropolitan Atlanta. The majority of cases are identified from records at local hospitals, supplemented by case-finding from free-standing pathology laboratories, outpatient clinics, physicians' offices, and death certificates. The present study concerns all cases of *in situ* or invasive breast carcinoma first diagnosed among females between 1979 and 1986.

Race- and age-specific incidence rates of *in situ* and invasive breast cancer by stage were computed for each of four consecutive two-year time periods between 1979 and 1986, using population estimates derived by the US Bureau of the Census[15] and the National Cancer Institute. The incidence rates were age-adjusted to the 1970 US population 20 years of age and older, and approximate 95 percent confidence intervals (CIs) were calculated.[16] Age-adjusted incidence rate ratios with corresponding approximate 95 percent CIs[17] were calculated for each subsequent time period relative to 1979–80, and tests for trends over time were performed with Poisson regression.[18]

Probability samples of registry abstracts for patients with invasive disease (n = 100 Blacks, 100 Whites) in each of two time periods, 1979–80 and 1985–86, were also reviewed to characterize the process that led to cancer detection.

Results

The overall average annual age-adjusted incidence rates of both *in situ* and invasive breast cancer among Whites rose during this study (Figure 1). The climbing incidence of invasive malignancies, however, was confined to patients with localized disease at diagnosis. Among Blacks, no increase in the age-adjusted incidence rate of *in situ* breast carcinoma was observed until 1985–86 (Figure 2). The corresponding incidence of invasive breast cancer, in contrast, rose consistently over time. The increase in incidence occurred mainly in patients with localized disease, except for a climb in regional disease during the most recent time period.

This paper, submitted to the Journal August 11, 1989, was revised and accepted for publication August 6, 1990.

For both races, incidence rates increased temporally in each of the age groups 20–49, 50–64, and 65 or over. Tables detailing the changes in rates over time will be provided upon request.

Age-adjusted incidence rates of *in situ* breast cancer more than doubled among Blacks from 1979–80 to 1985–86 (rate ratio [RR] = 2.3), and more than tripled among Whites (RR = 3.7). This increase was greatest for those aged 50 or older among Whites, and among those within the age group 50–64 among Blacks. For invasive breast malignancies, the temporal trends in incidence were more homogeneous across age groups. Overall, the rate ratios over time, with 1979–80 as the reference period, were greater for Blacks (45 percent increase) than Whites (26 percent increase).

Review of records for a sample of patients with invasive malignancies revealed that the proportion of patients who were asymptomatic or without a recorded symptom increased to 10 percent of both White and Black patients (Table 1). The majority of these women were diagnosed with a mammogram, either with or without an accompanying physical examination. The proportion of patients who were symptomatic but who were also diagnosed with a mammogram rose to 32 percent among Whites and 15 percent among Blacks (Table 1). Among Blacks, the increasing use of mammography was evident among patients with localized disease, but not among those with more extensive disease at diagnosis (Table 2). Among Whites, however, a substantial increase in the use of mammography was observed in both localized and nonlocalized disease categories.

Among Whites, about 2 percent of invasive cancers diagnosed in 1979–80 were asymptomatic (Table 1). Multiplication of this percentage by the age-adjusted invasive incidence rate for that time period (119.5 per 100,000) yielded an estimate of the age-adjusted rate of asymptomatic cancers (viz., 2.4 per 100,000). The corresponding estimate for Whites during 1985–86 was 15.1 per 100,000, or 40.2 percent of the total increase in breast cancer occurrence between these two time periods. The corresponding percentage for Black women was 25.4 percent. By similar reasoning, asymptomatic tumors reported as mammographically detected accounted for an estimated 20.1 percent of the increase among Whites and 12.8 percent among Blacks.

Discussion

The findings of increasing incidence rates of both *in situ* and invasive breast carcinoma in Atlanta are consistent with results from national surveillance data.[4] Also in accord with national trends,[4] among women with invasive malignancies, only those with localized disease demonstrated a substantial rise in incidence.

Although improvement in case ascertainment could produce an apparent rise in incidence, case ascertainment procedures did not change over time, and less than one percent of cases throughout this study were detected only from death certificates, suggesting virtually complete ascertainment at hospitals.

It has been shown that an increasing proportion of ductal carcinomas of the breast are detected by mammograms at the *in situ* stage.[13] In principle, mammography could lead to the detection of invasive cancers that would not be recognized otherwise. In the present study, however, mammographic detection of asymptomatic lesions accounted for only 20–40 percent of rising incidence among Whites and only 13–25 percent among Blacks.

The impact of mammography on earlier diagnosis of breast cancer was evident, however. The proportion of localized invasive carcinomas rose among Whites and Blacks, and the sampled abstracts revealed shifts toward mammographic diagnoses for localized disease among both races. These findings are in agreement with the results of previous studies, which have shown smaller tumor size, fewer lymph node metastases,[19] and earlier stage at diagnosis[20] among women with breast cancer detected by mammography screening.

Factors other than mammography could have contributed to the shift toward earlier stages of disease. In particular, heightened awareness of breast cancer[4,21] and increasing practice of breast self-examination[21,22] could result in earlier recognition of disease. Unfortunately, the medical records reviewed in this study did not include information on these health behaviors.

In summary, it does not appear that increased mammographic screening fully accounted for the rising incidence of breast cancer. Further work is needed to determine whether increasing prevalence of established risk factors or the emergence of new risk factors can be implicated. □

NIMH Fifth Annual Research Conference on Mental Disorders

The National Institute of Mental Health is planning a research conference on the classification, recognition and treatment of mental disorders in general health care settings serving children, adolescents, and adult patients. The conference, planned for September 23–24 in the Washington, DC vicinity, will be the fifth annual conference on this topic.

Research presentations are encouraged for special sessions on: 1) diagnosis and care of mental disorders in *special populations* (rural, minority, child/adolescent) who are served by general medical caregivers; and 2) *alcohol and substance use disorders* in general medical settings. Other topics of interest include:

- the classification and accuracy of mental and substance use disorder diagnoses;
- the recognition and management of mental and emotional disorders found in the chronically medical ill;
- the severely mentally ill in general health settings;
- effectiveness of pharmacologic, psychosocial or consultation-liaison services;
- patterns and outcomes of referral of general medical patients to mental health specialists.

Research treatment settings may include ambulatory primary care settings, medical/surgical inpatient services, nursing homes, and emergency wards.

Abstracts, due May 30, will be reviewed by a scientific advisory committee and NIMH staff. Priority will be given to abstracts on new, completed research. Work in progress with an expected completion date before the conference, and original reviews of the research literature, may also be submitted.

The Validity of Health Risk Appraisals for Coronary Heart Disease: Results from a Randomized Field Trial

Kevin W. Smith, MA, Sonja M. McKinlay, PhD, and John B. McKinlay, PhD

ABSTRACT

Background: **While health risk appraisals (HRAs) are becoming increasingly popular as tools for health assessment and health education, comparatively little is known about the accuracy of these risk estimates.**

Methods: **A field trial among 732 randomly selected adults ages 25 to 65 years was conducted to assess the validity of the risk scores produced by four widely used HRAs.**

Results: **Self-reported HRA risk scores for cigarette smoking and relative weight were generally accurate, but correlations between physiological measurements and scores for blood pressure, cholesterol, and physical activity were always lower than .51. Correlations between epidemiologic estimates of the probability of CHD death and HRA total risk scores ranged from .13 to .75; partial correlations adjusting for age, race, and gender ranged from .12 to .47.**

Conclusions: **The HRAs chosen for the field trial exhibited modest correlations with the CHD mortality risk predicted by the epidemiologic model. Mathematical errors made by respondents completing self-scored instruments and lack of knowledge regarding physiologic status decrease the accuracy of HRA risk estimates. (*Am J Public Health* 1991;81:466–470)**

Introduction

Health risk appraisals (HRAs) are designed to estimate a person's mortality or morbidity risk for various diseases based on such characteristics as medical history, blood pressure, and smoking habits. HRAs have become increasingly popular as health education tools. Recent estimates indicate that more than 200 organizations in the United States currently use HRAs to promote health awareness, and that between five and 15 million people have completed one of these instruments.[1] HRAs are also frequently included in work-site health promotion activities.[2] Despite the burgeoning popularity of HRAs, comparatively little is known about the validity of the risk estimates produced by them. Several recent reviews of HRA usage have stressed the need for further research on the accuracy of the predictions made by these instruments.[3-5]

In an earlier paper,[6] we examined the accuracy of the scoring systems employed by 41 different HRAs to estimate coronary heart disease (CHD) mortality risk. Correlations between HRA risk scores and epidemiologic estimates were found to be influenced by the sophistication of the HRA scoring system, the number of risk factors included in the instrument, the range of categories available for each risk factor, and the sensitivity of the scoring system to the effects of age and gender. Foxman and Edington[7] have also examined HRA accuracy with respect to mortality from all causes. These two studies based their assessments of HRA accuracy on physical examinations in the Framingham Heart Study and Tecumseh Community Health Study, respectively. Since the respondents who complete HRAs may or may not be aware of the appropriate values for risk factors, the use of actual physiological measurements in these studies is likely to have overstated the accuracy that would be obtained from self-reported risk scores.

This paper examines HRA validity based on self-reported data from a general population. Three questions are addressed: 1) How accurate are respondents' self-reports for HRA risk factors? 2) How accurate are HRA estimates of the risk of CHD mortality based on these self-reports? 3) To what extent is the validity of HRA risk scores affected by reporting errors and computational mistakes made by respondents?

Methods

A field trial of health risk appraisal instruments was conducted by the Cambridge Research Center of the American Institutes for Research in 1987. The trial was specifically designed to assess the reliability and validity of four representative HRAs in a general population. Respondents between the ages of 25 and 65 were identified through random digit dialing of 15 telephone exchanges in the Boston metropolitan area. Sampling and interviewing procedures for the field trial have been described elsewhere.[8]

During home visits, trained field technicians administered a standardized per-

sonal interview and one of the four HRAs to be evaluated by the project. Technicians were instructed not to help respondents complete HRA items or compute risk scores. The technician also measured blood pressure, height, and weight, and drew a venous blood sample for cholesterol analysis following the protocol established by the Centers for Disease Control (CDC). In-home physiological measurements have been shown to be as reliable and valid as those performed in a central location using standard equipment.[9]

Four widely used HRAs were chosen to represent the major types of computer-scored and self-scored instruments available in 1987: 1) Health Risk Appraisal (Centers for Disease Control), 2) The Heart Test (Arizona Heart Institute), 3) RISKO (American Heart Association), and 4) Determine Your Medical Age (Blue Cross/Blue Shield of New York). These were found to be among the most valid instruments within major HRA classifications in our previous work.[6] Since the field trial, the CDC instrument has been replaced by the Carter Center's "Healthier People" HRA.[10] The Carter Center's questionnaire and reporting format are similar to those of the earlier CDC version, but it uses an updated algorithm for assessing risk.

Each instrument requires a respondent to select categories that best describe personal habits, physiological status, and medical history. Point values or weights associated with these categories are then combined to produce an overall estimate of risk. In these four HRAs, total risk is summarized either by a heart-attack risk scale, with higher values representing greater risk, or by appraised age. Appraised age is the age at which the average mortality risk for all adults of the same gender and race is equal to the risk projected for a particular individual. If a person's appraised age is higher than his chronological age, that person has a greater than average chance of dying. The range of total risk scores and point values or weights for five major CHD risk items is shown in Table 1.

The CDC HRA, which requires computer processing, provides probability estimates for the 12 leading causes of death based on the Geller-Gesner method.[11] The Arizona Heart Institute's Heart Test and RISKO are self-scored instruments focusing on heart attack risk. In Determine Your Medical Age, appraised age is calculated by adjusting an individual's chronological age for medical history and lifestyle factors.

A standard psychometric definition for validity was adopted for this study; that is, that validity refers to the degree to which an instrument measures what it is intended to measure.[12,13] In order to assess the validity of a measure, some criterion or "gold standard" must be available for comparison. Table 2 shows the validation measures used in this study. Physiological values served as standards for three of the five CHD risk items. The standards for physical activity (kilocalorie expenditure for the previous week as calculated from the Harvard Alumni Activity Survey Scale)[14] and cigarette smoking were based on self-reports collected during personal interviews. HRA scores for heart attack risk or appraised age were compared to estimates from the NHANES I Epidemiologic Followup Study (NHEFS).[15] Separate NHEFS logistic models for men and women provide estimates of the probability of death due to coronary heart disease over a ten-year period based on a large (N = 4,013) representative sample of white adults.

Several statistical techniques can be employed to assess the extent of agreement or conformity between two measurements, including sensitivity, specificity, correlations, mean differences, and standard deviations for differences. Which technique is most appropriate remains a controversial issue.[16,17] However, the self-reported risk scores and the validation measures in this study cannot be directly compared because they were not measured on the same scale. Therefore, product-moment correlations between risk scores and validation measures were employed as the primary indicator of accuracy.[12]

As the criterion measure for CHD risk, the 10-year heart disease mortality probability for each respondent was calculated using the gender-specific NHEFS models. Physiological measures taken by field technicians, rather than self-reports, were used to make the logistic estimates as accurate as possible. According to the logistic models, a few respondents had mortality risks that were much higher than the risks for the great majority of cases. To prevent these outliers from distorting the correlation coefficients, the natural logarithm of the 10-year mortality risk per 100,000 persons was used in the analyses.

Three HRA total risk scores were computed for each respondent: 1) the score reported by the respondent, 2) the risk score corrected for mathematical errors, and 3) the score that would have been obtained on the basis of the blood pressure, cholesterol, height, and weight measurements taken by field technicians. The first of these scores does not apply to the CDC instrument, which is calculated by computer. Each of these three risk scores was then correlated with the log-

TABLE 3—Demographic Characteristics of Field Trial Participants and Nonparticipants*

transformed probability estimates derived from the NHEFS logistic model. Logarithmic transformations were also applied to the CDC probabilities. CHD mortality rates increase monotonically with age and are considerably higher for men than women. To remove these effects from the validity assessments, partial correlations were also computed for each HRA score, adjusting for age, gender, and race.

Results

Baseline interviews were completed by 732 of 1,276 eligible adults (57.4 percent) contacted for the field trial. A logistic regression analysis of response rates indicated that the probability of obtaining a completed interview was not affected by demographic characteristics (gender, race, age, and average income level in the telephone exchange), self-reported health status, or concern about the state of one's health. Similarities between field trial participants and eligible subjects who declined to be interviewed are shown in Table 3. The median age of the sample was 38 years. Respondents were somewhat younger and healthier than the general population because persons with diabetes, hypertension, or evidence of overt cardiovascular disease were screened out of the sample.

Validity of CHD Risk Factors

The first set of analyses focused on five specific CHD risk items. These analyses were restricted to respondents whose physiological measurements were completed during the baseline interview. Table 4 shows the correlations between self-reported risk scores and validation measures for each of the four HRAs. These results reveal some sharp distinctions among the individual risk factors. The coefficients for cigarette smoking and relative weight were always .6 or greater for each of the four instruments. On the other hand, none of the correlations for physical activity, blood pressure, or cholesterol were higher than .5. The HRA risk scores for these items accounted for less than 25 percent of the variance in the physiological measures. The smallest correlations were found for blood pressure and cholesterol. This occurs primarily because many people do not know the appropriate values and either assume that their levels are average or make inaccurate guesses. The magnitudes of these correlations were relatively consistent from HRA to HRA; there was more variation among different risk factors than among instruments.

Validity of Heart Attack Risk Scores and Appraised Age

The second set of analyses examined the validity of HRA scores for heart attack risk and appraised age. There are two potential sources of error in total risk scores. First, respondents may be unaware of the appropriate values for physiological measures. When asked to specify exact values during in-person interviews, only 27 percent of the respondents gave systolic blood pressure values within 10 mmHg of those recorded by the field technicians, and only 4 percent estimated their total serum cholesterol to within 20 mg/dl of laboratory readings.

For self-scored appraisal instruments, a second source of error lies in computational mistakes made by respondents when calculating their total risk scores. Many of the field trial participants had difficulty computing these scores (Table 5). Error rates were affected both by the mathematical skills required by each instrument (addition, subtraction, or division) and by respondents' educational attainment (persons without four-year college degrees were twice as likely to make mistakes as those with baccalaureate or advanced degrees).

To assess the effects of these potential sources of error, separate correlations were computed for the risk scores reported by respondents, scores corrected for mathematical errors, and the scores that would have resulted from the physiological measurements taken by field technicians. The last of these three scores is similar to estimates based on physical examination data evaluated in our previous study.[6]

The upper panel of Table 6 shows the correlations for each HRA based on all respondents who were able to calculate risk scores and had a complete set of physiological measurements. The CDC risk appraisal had the highest correlations. This computerized instrument uses a more sophisticated scoring algorithm than the other HRAs and was the only one of the four that, like the logistic models, provides probability estimates for CHD mortality over a ten-year period. The CDC estimates, however, were consistently higher than the risks predicted by the NHEFS models (average risks of 1,522 per 100,000 compared with 1,173 per 100,000). Determine Your Medical Age had the next highest set of correlations, even though this instrument is not designed specifically for heart disease. Mathematical errors played an important role in the validity of this HRA, as the average coefficient increased from .41 to .55 when respondents' mistakes were corrected. Determine Your Medical Age also benefits considerably from the fact that CHD risk increases greatly with age, so that any HRA based on appraised age should have a reasonably high correlation in this type of analysis.

The pattern of results was considerably different for the Arizona Heart Institute HRA than for the other instruments. The correlations for this HRA were always about .52, regardless of whether computational errors were corrected or actual physiological values were substituted for the respondent's choices. This probably occurred because comparatively few people completing this instrument made errors in their risk calculations and because cholesterol values are not re-

*Adjusted for respondent's gender, age, and race.

quired. RISKO had the smallest correlation with logistic estimates for the scores reported by respondents (.13), but in contrast to the other three HRAs, RISKO scores represent relative rather than absolute mortality risk.

A more refined assessment of validity can be made by examining partial correlations between HRA scores and the logistic estimates after controlling for age, gender, and race, as shown in the lower panel of Table 6. These three demographic characteristics consistently explained 85 to 90 percent of the variation in the log-transformed logistic rates. The resulting partial correlations were smaller than the unadjusted correlations in Table 5 for all HRAs except RISKO. The partials for self-reported Medical Age and RISKO scores were less than .2, but these coefficients more than doubled when mathematical errors were corrected. The magnitudes of the partial correlations also showed small improvements for three HRAs and a large increase for RISKO when physiological measurements taken in the field were substituted for the values selected by respondents.

Discussion

The results of this randomized field trial have several important implications for the accuracy of HRA instruments when used by a general population.

First, self-reported risk scores for cigarette smoking and relative weight appear to be accurate enough for use in HRAs. However, reports for physical activity, blood pressure, and cholesterol were frequently inaccurate when compared with more objective measures. Many people don't know their blood pressure or cholesterol levels and don't do a very good job of guessing what these values are. In the field trial, 27 percent of the sample reported systolic blood pressure values that were within 10 mmHg of the readings taken by field technicians and only 4 percent gave cholesterol values that were within 20 mg/dl.

The HRAs chosen for the field trial exhibited modest correlations with the CHD mortality risk estimates predicted by the NHEFS epidemiologic model. After adjusting for variations attributable to age, gender, and race, the partial correlations for all three of the self-scored instruments were approximately .4 when computational errors had been corrected. The partial correlation for the CDC HRA, the only instrument that produced probability estimates, was only slightly higher (.47). Moreover, like other HRAs based on the Geller-Gesner techniques, CDC's ten-year mortality risk predictions were consistently higher than those produced by the NHEFS data.[6,7] Several of the more recently developed HRAs incorporate logistic equations that may be expected to yield higher partial correlations than the field trial instruments.

The trial results also indicate that, when used in the field, the accuracy of the self-scored HRAs is attenuated by mathematical errors made by respondents and, to a lesser extent, by a lack of knowledge of the exact values for blood pressure, cholesterol, height, and weight. Computational errors substantially reduced the correlations for RISKO and Determine Your Medical Age, but not for the Arizona

Heart Institute instrument. This appears to be a function of the computational burden a self-scored HRA imposes on respondents. Determine Your Medical Age requires three mathematical operations (addition, subtraction, and division); RISKO, two (addition and subtraction), while the Arizona Heart Institute scores involve only addition. Computational errors and uncertainty regarding one's physiological status have also been found to lower the test-retest reliability of these HRAs.[8] Providing respondents with accurate physiological measurements and checking HRA calculations for errors will therefore improve both the reliability and the validity of self-scored risk estimates.

Finally, it should be noted that the analyses presented in this paper are restricted to CHD mortality. Since the risk factors for CHD are relatively well established, HRA risk estimates may be less accurate for other, less frequent causes of death and morbidity. ☐

Clinical and Epidemiological Features of Neurotoxic Shellfish Poisoning in North Carolina

Peter D. Morris, MD, MPH, Douglas S. Campbell, MD, MPH, Ted J. Taylor, PhD, and John I. Freeman, DVM, MPH

ABSTRACT

Background: In October 1987, a red tide due to *P. brevis* affected the North Carolina coast for the first time. The purpose of our study was to describe the clinical and epidemiological features of neurotoxic shellfish poisoning (NSP), an illness caused by eating shellfish contaminated with the neurotoxins of *P. brevis.*

Methods: Active surveillance was established for cases of NSP. A descriptive study of the NSP cases was then completed.

Results: Forty-eight persons, who had eaten oysters at 20 meals, met the case definition. A variety of gastrointestinal tract and neurological symptoms were reported. The illnesses were generally mild and of short duration, and there were no deaths. Forty-one (85 percent) affected persons lived in five communities located within a 70-kilometer area along the coast. Cases occurred from October 27 to December 9; 27 (56 percent) of the cases occurred before the first closure of affected shellfish waters on November 2. There was a significant increase in the illness attack rate with an increase in the number of oysters eaten.

Conclusions: Routine monitoring of coastal waters for *P. brevis* is needed to facilitate earlier recognition of red tides, closure of affected areas, and education of the public before substantial exposure to contaminated shellfish occurs. (*Am J Public Health* 1991;81:471–474)

Introduction

Neurotoxic shellfish poisoning (NSP) is an unusual syndrome characterized by paresthesia, reversal of hot and cold temperature sensation, myalgia, vertigo, and ataxia.[1–5] Other symptoms include abdominal pain, nausea, diarrhea, burning pain in the rectum, headache, bradycardia, and dilated pupils.[1–5] It is caused by eating filter-feeding shellfish (oysters, clams, coquinas, and other bivalve mollusks)[5] containing neurotoxins produced by the marine dinoflagellate, *Ptychodiscus brevis*[6] (formerly *Gymnodinium breve*[7]). Accumulation of neurotoxins in fish probably does not occur.[5]

P. brevis can also cause a respiratory irritation syndrome.[8] The dinoflagellates are easily lysed by the surf, releasing toxins that cause conjunctival irritation, rhinorrhea, and nonproductive cough in persons who are close to the water.

The health problems caused by *P. brevis* are associated with a red tide bloom.[3,4,8] Red tide is a discoloration of sea water caused by a proliferation of large numbers of dinoflagellates.[8] In late October 1987, the North Carolina coast was affected by a *P. brevis* red tide, the first such episode outside of Florida and Texas.[9] The source of the dinoflagellates was probably a red tide that occurred off the southwest coast of Florida in September. The organism was carried around Florida by the Florida current and then north along the east coast of Florida by the Gulf Stream. In late October, a strong inshore eddy of the Gulf Stream, later detected using satellite imagery, probably brought algae-laden water to the North Carolina coast. Under favorable reproductive conditions, the organism proliferated, resulting in an extensive red tide. By October 30, the characteristic discoloration, massive fish kills, and cases of the respiratory irritation syndrome were reported along the North Carolina coast. On November 2, the organism was identified, and the affected shellfish areas were closed. On November 4, the first official news release warned the public not to consume shellfish from affected areas.

In early November, the Environmental Epidemiology Section of the North Carolina Department of Environment, Health, and Natural Resources learned of several neurological illnesses that occurred following consumption of shellfish harvested from known red-tide-affected waters. To detect other possible cases of NSP in North Carolina, active surveillance was established. In this report, we describe the general clinical and epidemiological features of NSP cases detected in this manner.

Methods

Telephone contact was made with coastal county primary-care physicians, health departments, and emergency rooms; emergency rooms in referral hospitals for the coastal counties; and the

Headache	7 (15)	2 (0.5–12)	7 (2–24)

North Carolina Division of Marine Fisheries. Each facility was asked to report any neurological or gastrointestinal (GI) illnesses associated with the consumption of shellfish after October 23 (when the toxic dinoflagellate probably first arrived on shore). Telephone interviews were completed on persons reported through surveillance and persons identified by the surveillance cases who had eaten at the same shellfish meals. The following data were sought from each person: name; age; sex; race; weight; presence of a chronic illness; medication use; date, time, and location of harvest or purchase of shellfish; type of preparation of shellfish; date and time shellfish were eaten; type and amount of shellfish consumed; time of onset of symptoms; estimates of duration of symptoms; estimates of days of bed rest and days lost from work or school; when and where medical attention was sought; and type of medical treatment. The questionnaire included a list of symptoms previously associated with NSP.[2] In addition, the questionnaire included symptoms associated with two similar toxic dinoflagellate syndromes—paralytic shellfish poisoning and ciguatera fish poisoning.[2]

Shellfish (oysters, clams, or mussels) were considered toxic if they produced at least one case of illness characterized by any of the previously reported neurological symptoms of NSP—paresthesia, temperature sensation reversal, myalgia, vertigo, or ataxia. In addition, shellfish must have been harvested from a known red-tide-affected area (>5000 *P. brevis* organisms/liter of water detected by direct microscopic examination). A person who had eaten toxic shellfish was defined as a case if any of the previously reported neurological symptoms of NSP occurred within 24 hours of eating the shellfish and persisted for at least one hour.

A retrospective cohort analysis was completed on those persons who had eaten at toxic shellfish (oyster) meals. Fisher's exact test was used to compare illness attack rates in those exposed and unexposed to toxic oysters.[10] Among persons who had eaten toxic oysters, summary 95 percent confidence intervals were used to assess the effect of potential risk factors (number of shellfish eaten, age, sex, presence of a chronic illness, chronic use of a medication, or alcohol consumption with the meal) on the attack rate of NSP.[11] The Mantel-Haenszel chi-square test for trend was used to assess the change in attack rates with an increase in the number of shellfish eaten.[12]

Residual specimens of toxic oysters were collected whenever available for laboratory analysis by the Environmental Sciences Section, Division of Laboratory Services, of the Department. Shellfish specimens harvested from the same general areas as those that were eaten at all the other shellfish meals were also collected for analysis. Since a bioassay specific for *P. brevis* neurotoxins was not available, a standardized mouse bioassay was used on the specimens to test for the presence of neurotoxicity.[13] This bioassay is based on the time until death of mice injected intraperitoneally with crude toxin residues extracted from shellfish. Relative toxicity is expressed in mouse units (MU). One mouse unit is the amount of crude toxin residue that, on average, will kill 50 percent of test mice in 930 minutes. Any detectable level of toxin per 100 grams of shellfish meat was considered a positive test.

Results

Forty-eight persons, who had eaten at 20 different meals, met the case definition. Two other persons experienced several of the typical NSP neurological symptoms after eating oysters in two different restaurants, but they were excluded from analysis because shellfish harvest sites could not be determined.

The median incubation period was three hours (range, 15 minutes to 18 hours). GI and neurological symptoms tended to occur at the same time. The constellation of symptoms presented by the cases is shown in Table 1. Forty-five (94 percent) had multiple symptoms, and 34 (71 percent) had more than one neurological symptom. There were no instances of paralysis or respiratory arrest. However, a 43-year-old White female was admitted to an intensive care unit for severe symptoms of bilateral carpopedal tremor and myalgia; total body paresthesia; ataxia; and vertigo. These symptoms developed 9.5 hours after eating approximately 45 oysters. On neurologic examination, her physician found decreased sensation, decreased reflexes, and temperature reversal in both lower extremities. She was treated supportively and recovered completely, approximately nine hours after onset of illness.

The median duration of illness was 17 hours (range, one to 72 hours). Twelve affected persons (25 percent) required one day of bed rest, while only one required two days of bed rest. Six (12.5 percent) missed one day of either work or school. One patient was hospitalized, but there were no deaths.

The 48 affected persons had a median age of 43 years (range, nine to 66 years); 27 (56 percent) were male, and all were white. Forty-one of the affected persons (85 percent) lived in five communities located along a 70-kilometer coastal area in Carteret and Onslow counties. This was the first area to be affected by the red tide, and it consistently had some of the highest *P. brevis* cell concentrations throughout the bloom. Cases occurred from October 27 to December 9 and peaked on Novem-

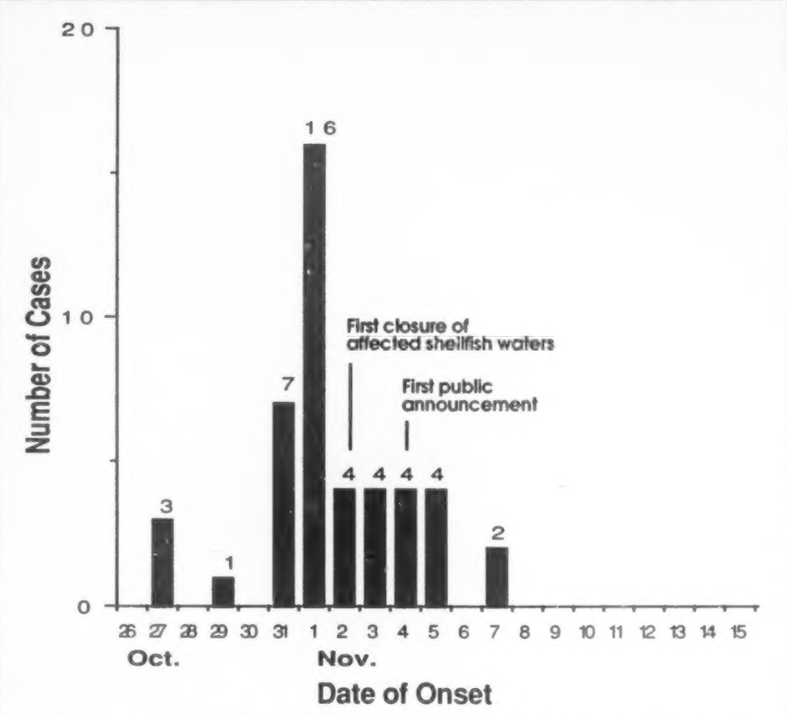

FIGURE 1—Date of Illness Onset, for 48 Neurotoxic Shellfish Poisoning Cases, North Carolina, 1987.

ber 1 (Figure 1). Three additional persons (not shown in figure) had eaten oysters harvested on October 31 and kept frozen until the date of the meal, December 8, when they became ill. Twenty-seven of the cases (56 percent) occurred before the first shellfish water closure on November 2.

All of the shellfish eaten at the meals were harvested within the same 70-kilometer stretch of coast discussed above. Forty-four of the affected persons (92 percent) had eaten shellfish harvested either by themselves or by another individual (relative, friend, or neighbor); whereas four (8 percent) had purchased oysters from fish markets. Two of the four had purchased oysters from a market before the shellfish harvest ban and the first public news release; the remaining two had purchased oysters from a fish market shortly after the ban and the news release.

Oysters were the only shellfish eaten at 19 of the 20 meals, while both oysters and clams were eaten at one meal. All cases were associated with freshly harvested shellfish, except for the one instance in December where frozen oysters were consumed. The shellfish consumed were generally described as being normal in appearance, taste, and smell. In all but one instance, the shellfish had been cooked before eating; cooking methods included steaming, roasting, baking, boiling, and frying.

A total of 98 persons had attended the 20 shellfish meals. The retrospective cohort analysis of these 98 persons revealed an illness attack rate of 56 percent (48/85) among those who had eaten oysters; none of the 13 persons who had not eaten shellfish became ill. None of the 25 case household members, who were not present at the shellfish meals, developed neurological or GI illnesses suggestive of NSP. Among those who had eaten oysters, the number of shellfish eaten was the only potential risk factor examined that significantly influenced the attack rate of NSP. The risk of developing NSP increased with the number of oysters eaten; this trend in disease risk was statistically significant (Table 2). The attack rates and relative risks in Table 2 were essentially unchanged after adjusting for age and the other potential risk factors examined in this study. Thus, only unadjusted data are shown in Table 2.

Samples of oysters eaten by four affected persons from two meals tested positive for *P. brevis* neurotoxins (35 and 60 MU, respectively). Samples of oysters harvested from the same general areas as those that were eaten by all the other cases also tested positive (mean, 62 MU; range, 48–170 MU).

Discussion

Since it was not possible to confirm the NSP cases with a specific laboratory test, some of the reported illnesses may have been due to other causes. However, this possibility was minimized by using a specific case definition—illness typical of previously reported NSP after eating shellfish harvested from a known red tide-affected area. In addition, epidemiological findings support the conclusion that the illnesses reported were due to NSP. First, none of the reporting sources were aware of any increase in neurological or GI illnesses unrelated to shellfish consumption during the time of the red tide bloom. Second, none of the 13 persons who had not eaten shellfish at any of the 20 meals developed neurological or GI symptoms suggestive of NSP. Third, none of the 25 case household members who were not present at the shellfish meals developed illnesses suggestive of NSP. Finally, among those who had eaten oysters, the illness attack rate rose with the number of oysters eaten. In addition to this epidemiological evidence, sample oysters tested positive for *P. brevis* neurotoxins, using the mouse bioassay.[13]

The affected persons developed a variety of neurological and GI symptoms similar to NSP cases previously reported from Florida.[3,4] However, we did find differences in the North Carolina cases that could provide insight in future clinical evaluations. Nausea and vertigo were more common in North Carolina than in Florida. In addition, some symptoms reported in North Carolina were not mentioned in the Florida reports; these included malaise, muscle weakness, tremor, and a choking sensation or throat tightness (this symptom was not included on the questionnaire but was spontaneously reported by several persons). Finally, 21 of the North Carolina cases (44 percent) had latency periods greater than three hours; whereas in Florida, all NSP cases had latency periods of less than three hours. These longer latency periods may have been due to differences in the relative concentrations of *P. brevis* neurotoxins. Indeed, analysis of neurotoxins from water samples taken during the North Carolina red tide bloom demonstrated a greater proportion of a slower acting component than had been found in a previous Florida red tide.[14]

TABLE 2—Number of Oysters and Risk of Neurotoxic Shellfish Poisoning, for Those Who Consumed Oysters, North Carolina, 1987

Number of Oysters	Cases	Total	AR (%)*	RR	95% CI
<12	2	15	13.3	1.0	
12–35	16	30	53.3	4.0	1.1–15.2
≥ 36	29	39	74.4	5.6	1.5–20.5

*AR = Attack Rate
Mantel-Haenszel chi-square = 15.9 $p < 0.000034$

Even though *P. brevis* was detected in shellfish waters until mid-February 1988, the number of cases dropped sharply on November 2, suggesting that the shellfish water closure and public news release were effective in preventing illness. Most of the cases occurred among persons who had eaten oysters harvested either by themselves or by a relative or friend, emphasizing the need to educate not only seafood merchants but also the general public about the dangers of harvesting and consuming shellfish from red tide-affected waters. Furthermore, most of the NSP cases lived along that section of the coast where the bloom started and where *P. brevis* reached its highest concentrations. These persons had easier access to toxic oysters, which is possibly the cause of this geographic clustering. It is therefore important to focus education measures on populations of coastal areas directly affected by red tide waters.

The effectiveness of shellfish water closures and public education as preventive measures depends on early detection of *P. brevis* in water samples. In North Carolina, more than a week passed from the time dinoflagellate cells were first carried to the coast until the first shellfish water closure and public news release. The characteristic discoloration of water, fish kills, and the respiratory irritation syndrome indicate the presence of a red tide and possible shellfish contamination and are thus useful warning signs. However, Florida officials, by routinely sampling coastal waters during the months when red tides tend to be more common, can usually detect levels of the organism high enough to contaminate shellfish (>5,000 organisms/liter of water), but not yet high enough to cause noticeable effects in the water (Florida Department of Natural Resources contingency plan for control of shellfish potentially contaminated by marine biotoxins. Bureau of Marine Research, St. Petersburg, Florida, 1985). This probably prevents cases of NSP.

Routine monitoring of coastal waters has now been established in North Carolina. The Gulf Stream is checked for inshore incursions or eddies by examining oceanographic frontal analyses received from the National Hurricane Center in Miami. These analyses are prepared thrice weekly from hourly infrared images taken by the Geostationary Operational Environmental Satellite series. These analyses are normally used to assist mariners who wish to either utilize or avoid the swiftly flowing Gulf Stream. Fishermen also use the analyses to pinpoint potentially good fishing areas. If a strong eddy occurs along the North Carolina coast, then sampling of relevant coastal waters for *P. brevis* is started immediately. Such a monitoring program should facilitate earlier recognition of possible future red tides, closure of affected areas, and education of the public before substantial exposure to contaminated shellfish occurs. ☐

Bone Cancer Incidence Rates in New York State: Time Trends and Fluoridated Drinking Water

37

ABSTRACT

Background: Recent animal studies of the potential carcinogenicity of fluoride prompted an examination of bone cancer incidence rates.

Methods: Trends in the incidence of primary bone cancers, including the incidence of osteosarcomas were examined among residents of New York State, exclusive of New York City. Average annual osteosarcoma incidence rates in fluoridated and non-fluoridated areas were also compared.

Results: Among persons less than 30 years of age at diagnosis, bone cancer incidence among males demonstrated a significant increase since 1955, while incidence among females has remained unchanged. A significant decrease in bone cancer incidence rates since 1955 was observed among both males and females age 30 years and over at time of diagnosis. Osteosarcoma incidence rates have remained essentially unchanged since 1970, among both younger and older males and females. The average annual age adjusted incidence of osteosarcomas (1976–1987) in areas served by fluoridated water supplies was not found to differ from osteosarcoma incidence rates in non-fluoridated areas.

Conclusions: These data do not support an association between fluoride in drinking water and the occurrence of cancer of the bone. (*Am J Public Health* 1991;81:475–479)

Introduction

Artificial fluoridation of public drinking supplies has resulted in an ongoing debate concerning the potential health effects of this practice. Proponents have emphasized the benefits to dental health from the artificial fluoridation of drinking water, while opponents have suggested that a variety of adverse health outcomes, including cancer, can result from this exposure.

Interest in the potential carcinogenicity of fluoride has resurfaced as a result of recently released findings from a National Toxicology Program (NTP) study of rodents with life-long exposures to fluoride. That study reported an increased incidence of osteosarcomas among male rats ingesting a high fluoride diet. Although the significance of these findings is unclear, the study has raised renewed questions about the association between fluoridated drinking water and bone cancers, particularly osteosarcomas, in human populations.

Several studies which have compared cancer mortality in fluoridated and non-fluoridated areas have determined that cancer mortality is unrelated to fluoride levels in drinking water.[1–6] However, the relationship between cancer incidence and fluoridated water has not been thoroughly examined. We were able to identify only two previous studies of cancer incidence and fluoridated water supplies.[1,7] Using data from the Second and Third National Cancer Surveys, Hoover *et al*,[1] compared cancer incidence for a fluoridated (Denver) and nonfluoridated metropolitan area (Birmingham). No significant differences in overall cancer incidence were apparent, nor were significant differences in bone cancer incidence observed. Kinlen and colleagues[7] reported no differences in the incidence of bone cancers among areas in England and Wales, and the United States, Holland, and New Zealand, with high and low fluoride levels in drinking water. An additional study of exposure to fluoride among an occupational cohort reported an elevated cancer incidence among exposed workers, attributable to an excess of respiratory cancers.[8] It is not possible to rule out smoking as the cause of this respiratory cancer excess since information on smoking histories was unavailable. No cases of bone cancer were reported in this study of occupational fluoride exposure.

Widespread artificial fluoridation of drinking water supplies in New York State began primarily during the 1950s and early 1960s. By analyzing data in the New York State Cancer Registry, it is possible to compare current bone cancer incidence rates with rates prior to widespread fluoridation. This paper presents data on time trends in bone cancer incidence, including the incidence of osteosarcomas, among residents of New York State, exclusive of New York City, and compares average annual osteosarcoma incidence rates in fluoridated and nonfluoridated areas.

Methods

The New York State Cancer Registry has been operational since 1940, when

This paper, submitted to the Journal June 25, 1990, was revised and accepted for publication October 18, 1990.

cancer became a reportable disease in NYS. Beginning in 1973, this population-based registry expanded coverage to include the New York City area, thereby encompassing all of NYS. While physicians, laboratories, and hospitals are required to report cancer cases, most cases in the NYS Cancer Registry and other cancer registries are reported by hospital tumor registrars and medical record administrators. Based on the results of special studies of hospital records, it is estimated that over 95 percent of all cancer cases in New York State, exclusive of New York City, are reported to the registry.[9]

Analyses were restricted to primary malignancies of the bone occurring among residents of New York State, exclusive of New York City, between 1955 and 1987. The New York City area was excluded due to lack of cancer data before 1973. Bone malignancies were coded to International Classification of Diseases, Ninth Revision (ICD-9),[10] site 170. Site 170 includes cancers of the bone and articular cartilage, but excludes carcinomas of any type other than intraosseous or odontogenic. Three separate comparisons of bone cancer incidence were undertaken.

The first comparison involved the calculation of average annual age-specific bone cancer incidence rates, between 1950 and 1987, for both males and females. Because of the distinct bimodal age pattern for bone cancers,[11] incidence rates were compared within two broad age categories: less than 30 years and 30 years and older at time of diagnosis. United States Census data were used to provide decennial (1960, 1970, 1980) population counts by age and sex for NYS,[12–14] while age- and sex-specific population estimates for intercensual years were furnished by the New York State Department of Health Bureau of Biometrics. Trends in incidence rates were evaluated by considering the slope of the regression line (t-test) using Statistical Analysis System (SAS) computer software.[15] Ninety-five percent confidence intervals for incidence rate ratios were calculated as described by Rothman.[16]

A second comparison involved the calculation of average annual age-specific osteosarcoma incidence rates, among males and females between 1970 and 1987. Histologic codes were assigned according to the Manual of Tumor Nomenclature and Coding[17] or more recently the International Classification of Diseases for Oncology.[18] Due to a different histologic classification scheme in use before 1970 it was not possible to distinguish histologic subtypes of bone cancers reported to the Registry prior to 1970. Trends in osteosarcoma incidence rates were also evaluated using the procedures described above.

Drinking water supplies in New York State contain no appreciable levels of naturally occurring fluoride. Thus, fluoridated water supplies are all artificially fluoridated. A third comparison evaluated average annual age-specific incidence rates for bone cancers and osteosarcomas, between 1976 and 1987, among males and females residing in fluoridated and nonfluoridated communities. Two metropolitan areas in New York State have maintained nonfluoridated drinking supplies: the City of Albany and Suffolk County.[19] Since less than 10 percent of the Nassau County population consumes fluoridated water, this metropolitan area was also considered to be nonfluoridated for the purposes of this study. Together, the 1980 population of these nonfluoridated areas (Albany, Suffolk County, Nassau County) was 2,707,540.[13] Since the nonfluoridated areas are urbanized communities, osteosarcoma incidence rates in these areas were compared with incidence in two groups of fluoridated communities: 1) counties located within standard metropolitan statistical areas (i.e. urbanized areas), and 2) counties not located within standard metropolitan statistical areas. Residents of nonmetropolitan areas are less likely to be served by a public water supply. Since these incidence rates were based on a limited number of cases (due to the infrequent occurrence of osteosarcomas), the standard error (SE) of each incidence rate was estimated by dividing the rate by the square root of the number of cases upon which it is based.[20]

Results

Between 1955 and 1987, 3,166 bone cancers were diagnosed among residents of New York State, exclusive of New York City (1,824 males, 1,292 females). About one-third (n = 1,100) of these cases occurred among persons less than 30 years of age at diagnosis (652 males, 448 females); 2,016 cases occurred among persons ages 30 and over at time of diagnosis (males 1,172, females 844).

Trends in Bone Cancer Incidence Rates

For bone cancers among persons less than 30 years of age at diagnosis, the slope of the regression line was significant among males ($p = 0.002$) with an observed increase in bone cancer incidence of 54 percent during the 1955–87 period. Among females (<30 years), bone cancer incidence increased 44 percent; however, the slope of the regression was not significant at the 5 percent level ($p = 0.07$). Further exploration of trends in bone cancer incidence among persons less than 30 years of age at time of diagnosis reveals that, relative to the period 1955–63, a significant increase in bone cancer incidence among males occurred only after 1969, while among females incidence was not significantly increased until the 1983–87 period (Table 1).

Bone cancer incidence rates among persons age 30 years and over at diagnosis show a significant decrease among both males (44 percent decrease, $p = 0.0001$) and females (33 percent decrease, $p = 0.0001$). Relative to incidence during the period 1955–1963, bone cancer incidence rates among males were significantly decreased during the period 1970–75 and thereafter (Table 1). Among females age 30 years and older at diagnosis, significant decreases in bone cancer incidence rates did not occur until after 1975.

Trends in Osteosarcoma Incidence Rates

Among persons less than 30 years of age at time of diagnosis, 196 and 113 osteosarcomas were diagnosed among males and females, respectively, between 1970 and 1987. While there was some variation in annual osteosarcoma incidence rates, between 1970 and 1987, among persons less than 30 years of age at diagnosis, the slope of the regression line was not significant among either males (16 percent increase, $p = 0.71$) or females (18 percent increase, $p = 0.45$). As shown in Table 2, osteosarcoma incidence rates did not differ significantly during three six-year periods between 1970 and 1987.

Between 1970 and 1987, 135 osteosarcomas were diagnosed among males and 103 osteosarcomas were diagnosed among females age 30 years or older at time of diagnosis. Based on the slope of the regression line, osteosarcoma incidence rates have been stable among both males (16 percent decrease, $p = 0.58$) and females (24 percent increase, $p = 0.29$) over 30 years of age at diagnosis. Osteosarcoma incidence rates did not differ significantly during three six-year periods between 1970 and 1987 (Table 2).

Bone Cancer, Osteosarcoma Incidence and Fluoridated Drinking Water

As shown in Table 3, average annual sex- and age-specific bone cancer and osteosarcoma incidence rates (1976–87) did not differ between areas with and without fluoridated drinking water supplies.

Discussion

Although changes in bone cancer incidence since 1955 are evident, these changes have not been consistent between age groups or between the two genders. Bone cancer incidence rates among males less than 30 years at diagnosis have increased since 1955, while no statistically significant change in incidence was observed among females in this age group. Among persons ages 30 years and older, significant decreases in bone cancer incidence were noted among both males and females since 1955. Incidence increases, which have occurred, have been re-

stricted to more recent time periods among the cohort of persons born after the initiation of widespread artificial fluoridation of water supplies suggesting that any potential association with fluoride must be differential by age. The increased bone cancer risk observed in younger persons could be consistent with lifelong exposures to fluoride including exposures at times when growth rates for skeletal tissue are at a peak. However, other findings from this study do not support an association between exposure to fluoridated water and bone cancers. The incidence of bone cancers and osteosarcomas was not found to differ between areas with and without fluoridated drinking water supplies.

The potential specificity of effect from fluoride exposure was also examined by evaluating trends in the incidence of osteosarcomas. The incidence of osteosarcomas reveal no significant changes among either males or females, in either age group, since 1970. An examination of osteosarcoma incidence, between 1976 and 1987, in areas which have remained nonfluoridated did not indicate any significant differences compared to areas supplied by fluoridated water sources.

The limited secular increases observed in the number of bone cancer cases and osteosarcoma cases suggest that any potential effect of fluoride is probably minimal. Among population subgroups demonstrating incidence increases, the estimated annual increase in rates of bone cancers and osteosarcomas was 1–2 percent. Despite the ubiquitous nature of fluoride exposures, bone cancer and osteosarcomas remain as relatively infrequent cancers.

As with most previous studies of potential health effects resulting from exposure to fluoridated drinking water, the present study utilizes an ecological design and lacks precise measures of exposures to fluoridated drinking water, and other fluoride sources, at an individual level. Further, this study has not attempted to account for population mobility and movement between fluoridated and nonfluoridated areas. While most fluoridation of water supplies occurred during the 1950s and 1960s, some communities across New York State have initiated fluoridation of drinking water supplies at later times.

Although these data do not demonstrate consistent shifts in the incidence of bone cancers or osteosarcomas, recent increases in bone cancer incidence relative to the 1955–63 period are evident, particularly among younger persons. At this time it is not possible to establish an association between fluoride and bone cancer incidence. The potential role of fluoride in the incidence of bone cancers might be more thoroughly investigated using an analytic study design allowing more careful assessment of residential history to minimize misclassification of exposure to fluoridated drinking water and an examination of fluoride exposure from sources other than drinking water. ☐

Federal Hazardous Waste Law Plagued by Ambiguities, says Report

A portion of the 1986 federal law requiring each of the 50 states to ensure the availability of hazardous waste treatment or disposal facilities over the next 20 years has been plagued by ambiguities, unanswered policy questions, and at least one lawsuit, according to a report to the US Environmental Protection Agency (EPA) by a Tufts University researcher. The report by Sharon N. Green, senior environmental research analyst at Tufts' Center for Environmental Management (CEM), recommends that Congress reassess the need for hazardous waste treatment and disposal facilities, given uncertainties about waste generation and management over the next 20 years.

The report cites data from 13 Northeast states projecting an 18 percent decline in hazardous waste generation by the year 2009, based on economic forecasting, waste reduction programs, expected new regulations, and contaminated site cleanups.

In her report, Green suggests a 15-point set of recommendations, including that the goals of the current provision be clarified to explicitly address waste reduction, facility siting, and attaining geographic equity for waste management services.

Other recommendations in the report, released in December 1990, include:

- Congress should consider state and federal roles in providing hazardous waste management services, given that responsibility for waste generation and management currently rests with the private sector.
- Congress should reconsider the appropriateness of threatening non-complying states with the loss of federal funds for hazardous waste cleanup projects.
- EPA should provide additional guidance to states in preparing hazardous waste projections.
- Data collection and planning methods among the states should be standardized.

"Capacity assurance planning probably will become a viable public policy only if significant revisions are made to the structure and function of the provision and implementation process," Green concludes in the report.

Neonatal Diarrhea at a Maternity Hospital in Rangoon

Daw Tin Aye, MBBS, Dip Bact, David A. Sack, MD, I. Kaye Wachsmuth, PhD, Daw Thein Kyi, MBBS, DCH, and Shin Min Thwe, MBBS

ABSTRACT

Between 1981 and 1986, 1,540 infants born at the Central Women's Hospital in Rangoon were transferred to the Sick Baby Unit because of diarrhea (15.4 per 1,000 live births). Rates among cesarean infants were five times as high as those of infants born vaginally (51.0 and 10.3 per 1000 live births, respectively). One hundred eighty-four of the infants with diarrhea died (case fatality rate = 12 percent). We conclude that neonatal diarrhea is endemic in this large maternity hospital in Burma, and that control efforts should be targeted especially to cesarean and low birthweight infants. (*Am J Public Health* 1991; 81:480–481)

Introduction

Neonatal diarrhea was an important problem in American and Western European hospitals in the 1940s and 50s[1-6]; in recent years it has become relatively rare. The reported episodes of diarrhea tended to occur in clusters and were often associated with particular serotypes of *E. coli* which became known as enteropathogenic *E. coli* (EPEC).[7-10]

In developing countries diarrhea is a major endemic public health problem with an estimated five million deaths annually.[11] The bulk of the cases occur between the ages of six months and five years and most strategies for diarrheal disease control are targeted to this age group. Relative to this massive public health problem, neonatal diarrhea occurring in children born in hospital appears to be a relatively minor one.

Nevertheless, increasing numbers of children are born in developing country hospitals. A previous three-month survey in two Rangoon maternity hospitals found neonatal diarrhea to be the leading cause of transfer to the Sick Baby Unit (SBU) and the largest single cause of death among infants dying in the SBU (unpublished, Nyunt Nyunt Wai). Nevertheless a literature search based only on MEDLINE failed to find articles dealing with nosocomial neonatal diarrhea in developing countries. We therefore initiated this retrospective study to describe certain features of the problem.

Methods

The study was carried out at Central Women's Hospital, the largest of the hospitals serving maternity patients in Rangoon, Burma with about 16,000 deliveries annually. Formerly, newborn infants were cared for in nurseries separated from the mothers, and mothers and infants remained in hospital routinely for four to five days. During the period of the study, policies were introduced to promote "early discharge" (routine discharge one or two days after delivery) and "rooming in." Infants were said have "rooming in" if they were cared for by their mothers and stayed in cribs at the mother's bedside in large wards rather than residing in ward nurseries separated from their mothers except for feeding time. For infants born by cesarean section, these changes in policy did not apply and infants were for the most part cared for in nurseries by nurses.

This analysis is based on a review of the log from the SBU. Data include all admissions to the unit between 1981 and 1986 with diarrhea as the admitting diagnosis. The total numbers and types of delivery, obtained from annual hospital records, were used as denominators in calculating rates. Using the monthly totals which were available for the years 1983 through 1986, an estimate was made of the monthly distribution of deliveries for the period 1981–86.

*Rate in cases per thousand live births

Episodes of mild diarrhea in which the infant was not transferred to the SBU would not have been detected in this surveillance, nor would episodes occurring after discharge if the child did not return to the same hospital. This review therefore underestimates the numbers of cases actually occurring, but there was no apparent bias over time since the record-keeping and referral system remained constant.

Data analysis was performed using Crunch Interactive Statistical Package Version 3.0 with a PC DOS microcomputer. Statistical tests used were chi square, Fisher's exact or Mann Whitney tests where appropriate.

Results

During the six years under study, 1,540 infants were admitted to the SBU because of diarrhea. The annual number of cases ranged from 193 to 368 (rates of 11.2 to 22.4 per 1,000 live births). Overall rates for the first two years were higher than for subsequent years (Table 1). The monthly rates were higher during the post monsoon dry season (rates averaged 17.5 per 1,000 live births, October–January) and lower during the hot monsoon season (rates averaged 13.5 per 1,000 live births for May–August).

The overall yearly rates decreased during the period of study associated with a decrease in vaginal delivery rates. By contrast the rates associated with cesarean section were higher and remained unchanged (Table 1). Overall, infants born by section had a five times higher risk of developing diarrhea than those born by vaginal delivery (95% CI = 4.5, 5.5).

One hundred eighty-four (12 percent) of the infants with neonatal diarrhea died. Fatal cases tended to be older when admitted to the SBU (median of seven days for fatal cases vs six days for nonfatal, $p < .001$), to be smaller at birth (relative risk for birthweight < 2.3 kg = 4.6 (C.I. = 3.5, 6.0)). Infants with larger birthweights (> 3.6 kg) were also at higher risk (relative risk = 2.7 (C.I. = 1.2, 5.8, Fisher's exact = 0.036) when compared to those with birthweights between 2.3 and 3.6 kg. Although infants born by section were at a higher risk of diarrhea, they were not at a higher risk of dying with diarrhea. Case fatality rates were not different according to sex or ethnic group, but infants born of mothers with more than seven previous pregnancies were at higher risk ($p = 0.02$).

The available records did not permit a comparison of the case fatality rates of different clinical syndromes or of the possible benefits of specific forms of treatment on the case fatality rates.

Discussion

This study has demonstrated that diarrhea sufficiently severe to lead to transfer to the SBU was common in this Rangoon hospital between 1981 and 1986. The case fatality rate of 12 percent reinforces the severity of the problem. Cesarean section was the most prominent risk factor for diarrhea identified in the study (RR = 5.0). These infants tend to stay in the hospital longer, to be handled more by hospital staff and less by mothers, and to be fed more formula and less breast milk than other infants.

For children born by vaginal delivery, the rates of neonatal diarrhea decreased three-fold during the period of study. This decrease may have been related to "rooming in" and "early discharge" policies; however, we were not able to determine if these policies were effective, since the changes were phased in over a prolonged period and did not allow for a "before–after" analysis.

There are obvious limitations in the study which need to be addressed. As a retrospective study the cases detected likely underestimate the problem. Case definitions depended on the diagnosis of "diarrhea" at the time of transfer, rather than an actual description and quantitation of symptoms. Cases were not evaluated bacteriologically to determine the causative agents. Finally, there may be other relevant risk factors (types of formula, hand washing, etc.) which were not evaluated.

Nevertheless, the study clearly documents the importance and endemicity of the problem and suggests the need for further research as well as control strategies based on observations of current practice. ☐

Effect of Hospital Utilization Review on Medical Expenditures in Selected Diagnostic Areas: An Exploratory Study

Thomas M. Wickizer, PhD

ABSTRACT

Quarterly claims data on 43 insured groups were analyzed through multivariate techniques to explore whether the effects of hospital inpatient utilization review vary across selected broad diagnostic areas. Findings suggest that utilization review was associated with decreases in expenditures of approximately 15 percent for diagnoses within the surgical area, a lesser decrease within the mental health area, and still lesser decrease within the medical area. However, these measurements are imprecise both because of the small numbers and the aggregated diagnoses in each category. (*Am J Public Health* 1991;81:482–484)

Introduction

Hospital inpatient utilization review (UR) has assumed a prominent role as a private cost containment activity[1,2]; 65 percent of group insurance plans now operate under some form of UR.[3] UR evaluative research has produced mixed results,[4] with some studies finding large reductions in hospital use associated with UR[5–10] and other studies finding little if any effect.[11–15] Unfortunately, many of the UR evaluations suffer from methodological problems that raise questions about the reliability of the findings.[4,16]

One recently initiated study, conducted by the present author and colleagues, used multivariate techniques to analyze claims data on 223 insured groups. The study found UR was associated with significant reductions in hospital admissions, inpatient expenditures, and total medical expenditures.[17,18] However, the question of whether UR may have different effects across diagnostic categories was not examined, nor has this question been examined by other studies. The purpose of this paper is to report the findings of such an analysis.

Methods

The UR program analyzed, described in more detail elsewhere,[19] was established in 1983 by CNA Insurance Companies of Chicago and made available to policyholders as a benefit plan option. It consists of preadmission authorization and concurrent review and is compulsory for all employees and dependents. Patients failing to comply with UR procedures are subject to financial penalties. Physicians and hospitals are not subject to penalties.

The unit of observation for the analysis is the insured group. Expenditure data covering the period 1984 through 1986 were collected for selected diagnostic categories on 43 groups that adopted UR after operating without any cost containment program. Well-distributed geographically and representative of the under-65 population in terms of hospital use, these groups were selected for study because they provide longitudinal data (pre- and post-UR data) that permit the use of an efficient method of analysis. (Because of resource limitations, it was not possible to collect claims data by diagnosis for all 223 groups included in the larger study.) The average group includes approximately 1,300 insureds, comprising 550 employees and 750 dependents.

Quarterly claims data on the 43 groups were pooled, making 443 usable and complete observations available for analysis. To examine the effects of UR across diagnostic areas, measures were created representing mental health services, medical services, and surgical services. These measures were constructed by summing expenditures over selected diagnostic categories for which the insurance carrier routinely collected claims data. The term diagnostic area is somewhat imprecise. In general, it represents a set of conditions for several related ICD-9-CM diagnostic categories, but it bears no direct relationship to diagnosis related groups (DRGs) or other diagnostic classifications.

For the *mental health area*, expenditures were summed over alcohol, drug abuse, psychoses, and neuroses. For the *medical area*, expenditures were summed over diabetes, hypertension, infectious and allergy diseases, obstructive pulmonary disease, viral infections, and cutaneous diseases of the skin. For *surgical services*, expenditures were summed over benign neoplasms, diseases of the esophagus and stomach, diseases of the bones and cartilage, and musculoskeletal injuries.

Address reprint requests to Thomas M. Wickizer, PhD, Department of Health Services, SC-37, University of Washington, Seattle, WA 98195. This paper, submitted to the Journal March 13, 1990, was revised and accepted for publication August 27, 1990.

Descriptive information on the expenditure measures is presented in Table 1. The measures, which capture all inpatient as well as outpatient covered charges, represent services accounting for approximately 40 percent of total nonobstetric expenditures. Surgical services have the largest proportion of cases (28 percent) with quarterly expenditures over $30 per insured person. Included in the analysis is a set of 16 covariate factors, described in detail elsewhere,[19] representing employee population characteristics, health care market factors, and benefit plan features (see Appendix).

UR is measured by a binary variable that takes on a value of 1 if a group operated under UR during a given quarter, and 0 otherwise. It was not possible to distinguish preadmission authorization from concurrent review for purposes of analysis.

Ordinary least squares (OLS) regression was used to estimate a covariance model, constructed by differencing each observation from its time mean.[19–21] This model, which uses within-group (over time) variance to identify parameters, produces the same estimates as the standard fixed-effects (or least squares dummy variable) model but does not require inclusion of group-specific dummy terms, thereby saving degrees of freedom and improving computational efficiency. Since aggregate data collected over time were being analyzed on groups differing in size, procedures were performed to test for heteroscedasticity[22] and serial correlation.[23] The model's error terms were found to be heteroscedastic, and a standard weighting procedure was performed on the data to correct the standard errors. Specification tests revealed no evidence of serial correlation.

Three equations were estimated, one for each of the three services, with the covariate factors and the UR term included on the right hand side of the equations, in addition to a set of quarter dummy variables included to control for unmeasured temporal factors.

Results

The results of the analysis are presented in Table 2. As indicated, UR was associated with somewhat lower expenditures ($p < .07$) in the surgical area; after adopting UR the average group's expenditures for this diagnostic area declined by approximately 15 percent. This estimated percentage reduction implies an absolute reduction in surgical expenditures of ap-

TABLE 1—Descriptive Information on Dependent Measures (N = 433)

Measures	<$10.00 per Insured Person per Quarter[a]	$10.00 to $19.99 per Insured Person per Quarter	$20.00 to $29.99 per Insured Person per Quarter	>$30.00 per Insured Person per Quarter
Expenditures on Medical Services[b] (%)	109 (25)	184 (43)	88 (20)	52 (12)
Expenditures on Surgical Services (%)	57 (13)	148 (34)	106 (25)	122 (28)
Expenditures on Mental Health Services (%)	226 (52)	76 (18)	60 (14)	71 (16)

a) Expenditure data were adjusted by the Medical Care Price Index (MCPI) to reflect January 1985 prices.
b) The means and standard deviations (SD) for the three measures are: 1) Medical Expenditures, mean $17.78, SD $12.06; 2) Surgical Expenditures, mean $25.55, SD $21.32; and 3) Mental Health Expenditures, mean $16.16, SD $20.83.

TABLE 2—The Effects of UR on Expenditures for Three Diagnostic Areas: Mental Health, Medical, and Surgical Services (N = 433)

Measures[a]	Medical Expenditures	Surgical Expenditures	Mental Health Expenditures
Intercept	0.142* (0.087)[b]	0.131 (0.095)	0.261 (0.244)
% Female Employees under Age 30[c]	0.100 (0.173)	0.134 (0.193)	−0.204 (0.489)
% Male Employees Ages 30 to 50	0.023 (0.046)	0.058 (0.051)	0.157 (0.131)
% Female Employees Ages 30 to 50	0.005 (0.137)	−0.105 (0.152)	0.428 (0.386)
% Male Employees over Age 50	0.012 (0.029)	0.024 (0.032)	−0.015 (0.081)
% Female Employees over Age 50	−0.155 (0.300)	0.033 (0.332)	−0.597 (0.845)
% Childbirth/Pregnancy Expenditures	−0.901* (0.563)	−0.277 (0.623)	−0.086 (1.585)
% Heart Disease Expenditures	−0.298 (0.635)	−0.164 (0.703)	0.648 (1.789)
HMO Penetration Rate	0.015 (0.026)	0.037 (0.028)	−0.015 (0.072)
Office-Based Physicians per 1,000 Population	1.265 (0.917)	−0.822 (1.014)	−1.466 (2.584)
% General Practice Physicians	−2.246 (1.956)	−1.397 (2.164)	−0.841 (5.511)
Hospital Occupancy	−0.028** (0.013)	−0.029* (0.015)	−0.038 (0.037)
% Charges Covered for Semi-Private Room	0.001 (0.002)	−0.001 (0.003)	0.010 (0.007)
% Charges Covered for Hospital Outpatient Services	0.004 (0.003)	−0.000 (0.004)	−0.021** (0.010)
% Charges Covered for Physician Office Services	0.002 (0.005)	−0.001 (0.006)	−0.014 (0.016)
Deductible	−0.014 (0.017)	0.034* (0.019)	0.084* (0.049)
Utilization Review[d]	−0.062 (0.097)	−0.157* (0.108)	−0.146 (0.274)

NOTE: R^2 is not shown because this does not provide a meaningful indication of the model's explanatory power for mean-differentiated equations.
a) The coefficients of the quarter dummy variables are not included in Table 2 for economy of presentation.
b) Standard errors are shown in parentheses.
c) The reference variable is % Male Employees under age 30.
d) Since the dependent variable is measured in logarithms, the coefficients of the utilization review (dummy) variables can be interpreted as approximate percentage differences. The actual percentage difference in expenditures pre- versus post-UR is slightly lower than indicated by the coefficients. For example, the coefficient −0.157 for the surgical expenditure equation implies a 14.7 percent reduction in expenditures.
*$p < .10$; **$p < .05$

proximately $17.25 per insured person per year. Although the estimated UR coefficient for the mental health area is almost as large, it is not statistically significant due to the large standard error estimate. It appears UR has a less important effect on medical expenditures. As Table 2 shows, with few exceptions the covariate factors are not statistically significant.

Discussion

This exploratory analysis has sought to contribute to an improved understanding of an important question regarding the effects of hospital UR. The findings suggest UR's effects vary across diagnostic areas, and that UR may be more effective in reducing expenditures on diagnoses likely to involve surgical services than other services, especially medical services. One plausible explanation for this finding is that UR protocols may be better developed for surgical cases than for other cases. To work effectively, UR must have clinical protocols that can be followed and used to establish the need for hospital care. Such protocols may be better developed for surgery than other areas, which may explain, in part, why UR appears to be more effective for cases likely to involve surgical services. However, given the limitations of the data, these findings should be considered preliminary. Future research should conduct analyses using more complete and detailed data to examine this question in greater depth. ☐

Tracking Progress toward National Health Objectives in the Elderly: What Do Restricted Activity Days Signify?

Delia Scholes, PhD, Andrea Z. LaCroix, PhD, Edward H. Wagner, MD, MPH, Louis C. Grothaus, MA, and Julia A. Hecht, PhD

ABSTRACT

Restricted activity days is the measure by which the 1990 health objectives for prevention of functional disability in older adults will be evaluated. Yet its significance in older populations is poorly understood. We evaluated its use as an outcome measure for a randomized trial designed to impact upon physical function in elderly HMO enrollees. As predicted, restricted activity days was more correlated with physical disability measures than with other health status measures. Distributional properties and rates of missing data were shortcomings. (*Am J Public Health* 1991;81:485–488)

Introduction

In 1979, the US Surgeon General's report[1] designated the prevention of functional disability as the principal goal of health promotion in older adults. Restricted activity days (RAD), a standard item on the National Health Interview Survey, was chosen as the primary measure of disability to be monitored with the goal of achieving a 20 percent reduction by 1990. Evaluation of progress toward this goal is hampered because the meaning of RAD as a measure of health status in the elderly remains uncertain.[2,3] In younger age groups, RAD reflect transient loss of ability to perform social roles at work, home, or school, usually because of a physical limitation. In the elderly, many of whom are retired, usual activities are more variable. For this reason, several investigators have called for a better understanding of the appropriateness and usefulness in the elderly of such traditional health status measures as RAD.[4-6]

Because of the Surgeon General's 1990 objectives, we chose RAD as a primary outcome measure for an ongoing randomized controlled trial of health promotion involving nearly 2,300 older adults. We hypothesized that RAD would be more strongly correlated with measures of physical disability than with measures of mental, social, and global self-perceived health. Since there has been some speculation that days spent in bed might be a better measure of health status than RAD,[7] we compared the associations of both variables with these other health status measures.

Methods

The study setting is Group Health Cooperative (GHC) of Puget Sound, an HMO (health maintenance organization) located in western Washington State. At the study's inception in 1987, approximately 11 percent of enrollees were age 65 or older. This report is based on data from 2,289 enrollees, 36 percent of a random sample of 6,328 seniors, who returned completed baseline questionnaires and agreed to participate in the trial.

The questionnaire covered a broad range of health beliefs, behaviors, and conditions and included a number of standard single-item measures and multi-item scales. Information was obtained on the number of RAD and days spent in bed for the preceding 12 months using the questions described in Table 1, Section A.

For comparison with RAD and bed days we selected a number of baseline measures of physical health (Table 1, Section B), several measures of mental and social health (Table 1, Section C), and two self-evaluations of health status (Table 1, Section D). Spearman rank correlation coefficients were used to assess the association between the disability day variables and the other health status measures. Measures within each health status domain (physical, psychosocial, and self-evaluated health) were correlated with each other and within-group correlations were compared with correlations of each measure with disability days.

To explore reasons for non-participation in the trial, we interviewed a random sample of 175 non-participants by telephone using an abbreviated version of the same questionnaire. Nonparticipants were similar to participants with respect to age, gender, the prevalence of chronic disease, and number of RAD. They had less education, lower incomes, higher rates of smoking, worse self-perceived health, and less participation in social activities.*

TABLE 1—Selected Health Status Indices from Senior Baseline Questionnaire

Health Status Measure	Description and/or Item Content	Source
A. Disability Days		
1. Restricted activity days	Two items: "In the past 12 months, did you cut down the things you usually do, such as going to work or working around the house, because of illness or injury?" IF YES: "How many days did you cut down on the things you usually do because of illness or injury?"	Adapted from NHIS[8]
2. Days spent in bed	Two items: "In the past 12 months, did you ever stay in bed because of an illness or injury?" IF YES: "How many days did you stay in bed at least half the day because of illness or injury?"	Adapted from NHIS[8]
B. Physical Health Measures		
1. Functional limitations	Guttman scale of seven daily living activities: "For how long (if at all) has your health limited you in each of the following activities? (1) The kinds or amounts of vigorous activities you can do . . . [least impaired] . . . (7) Eating, dressing, bathing or using the toilet [most impaired]". Coefficient of reproducibility = .91, coefficient of scalability = .61.	Adapted from Ware[9,10]
2. Illness	Single item: "In the past 12 months, have you had a major personal illness?"	
3. Hospitalization	Single item: "In the past 12 months, were you ever in the hospital overnight for physical health problems?"	
4. Pain	Single item: "We would like to find out about any physical pain you may experience in your daily life. Below is a scale from 0 (no pain) to 10 (very severe pain). Please place an 'X' on the line in the spot that most closely represents how much pain you experience on a daily basis."	Ware[11]
5. Symptoms	13 questions about a range of symptoms experienced in the past week: e.g. "'I felt dizzy or lightheaded when I sat up or stood up"; "I had stomach cramps."	Developed for the study
6. Role limitations	Seven item scale on short-term physical limitations: "During the past 4 weeks, have you had any of the following problems with your work or other daily activities as a result of your physical health? a. Were limited in the kind of work or other activities you usually do?; g. Required special assistance (the assistance of others or special devices) to perform the activities you usually do."	Ware[10]
7. Heart Trouble	Single item: "Here is a list of medical conditions which usually last for some time. Have you had any of these conditions in the past 12 months?" Affirmative to "Heart trouble".	Belloc[12]
C. Social/Psychological Measures		
1. Life Satisfaction	11-item scale: "Below each question is a scale from 0–10, where 0 is "very satisfied" and 10 is "very dissatisfied". Please place an 'X' on the line by the number that most closely represents your response to each question."	Patrick[13]
2. Positive Affect/Pep and Vitality	Combined score from 10-item Positive Affect subscale and a number of items from a second subscale (Pep and Vitality): "During the past month . . . (a) how much of the time have you felt that the future looks hopeful and promising? . . . (m) how much energy, pep or vitality did you have or feel?" (6 response categories)	Adapted from Veit[14]
3. CES-D	10-item adaptation of the Center for Epidemiological Studies Depression Scale. "Please indicate by circling the appropriate response how often you have felt this way during the past week: (a) I was bothered by things that usually don't bother me . . . (j) I could not 'get going'."	Adapted from Radloff[15]
4. Stress	Single item: "Pictured below is a scale from 1 (none) to 10 (a great deal). Which number on the scale best represents how much stress you have been under for the past year?	Bailey[16]
5. Social Support	Single item: "Do you belong to a close circle of friends, a group of people who keep in touch with each other?"	Morgan[17]
6. Nervous Condition	Single item: "Here is a list of medical conditions which usually last for some time. Have you had any of these conditions in the past 12 months?" Affirmative to "Chronic nervous or emotional problems".	
D. Self-Evaluations of Health		
1. Self Perceived Health	Single item: "Would you say, in general, your health is (1) excellent . . . (5) poor?"	Ware[10]
2. Current Health Outlook	9-item subscale of General Health Perceptions Index: e.g. "My health is excellent"; "I have been feeling bad lately." (5 response categories)	Ware[10]

Results

Missing Values

In the 2,289 participants with completed baseline questionnaires, 11 percent of responses on RAD and 4 percent on bed days were missing. Missing data were more frequent for both measures among older respondents and those with poorer self-evaluated health (Figure 1.a., 1.b.).

Baseline Distribution of RAD and Bed Days

Both disability day variables had highly skewed distributions, as has been found for many measures of physical health in community-dwelling older populations.[14] Seventy-four percent of respondents reported no RAD and 73 percent reported no days spent in bed in the past 12 months.

Other Health Status Measures

Spearman correlations of RAD and bed disability days with selected measures of physical, psychosocial, and self-evaluated health status are presented in Table 2. Restricted activity days and bed days were highly correlated (.61); when the subset of RAD due to bed days was excluded, the correlation was .53. As hypothesized, the number of RAD was most strongly correlated with indicators of physical health (correlations ranged from .20 to .48), including the other two disability measures, functional and role limitations (r's = .34 and .39, respectively). Within-group correlations among physical health status measures ranged from .11 to .60.

Moderate correlations between RAD and the two self-evaluations of health were also found: .24 for self-reported health and .30 for current health outlook. However, these two measures were more highly correlated with each other (.68). The weakest associations with RAD were for the social support and mental health measures. Restricted activity days was more strongly correlated than bed days with all the physical health measures, except for hospitalization in the past 12 months (Table 2).

Our assessment of correlations between RAD and a subset of these variables in the sample of nonparticipants showed findings similar to the larger sample; RAD continued to be more strongly correlated with the available physical health status measures and had stronger correlations than bed days with most health status measures.

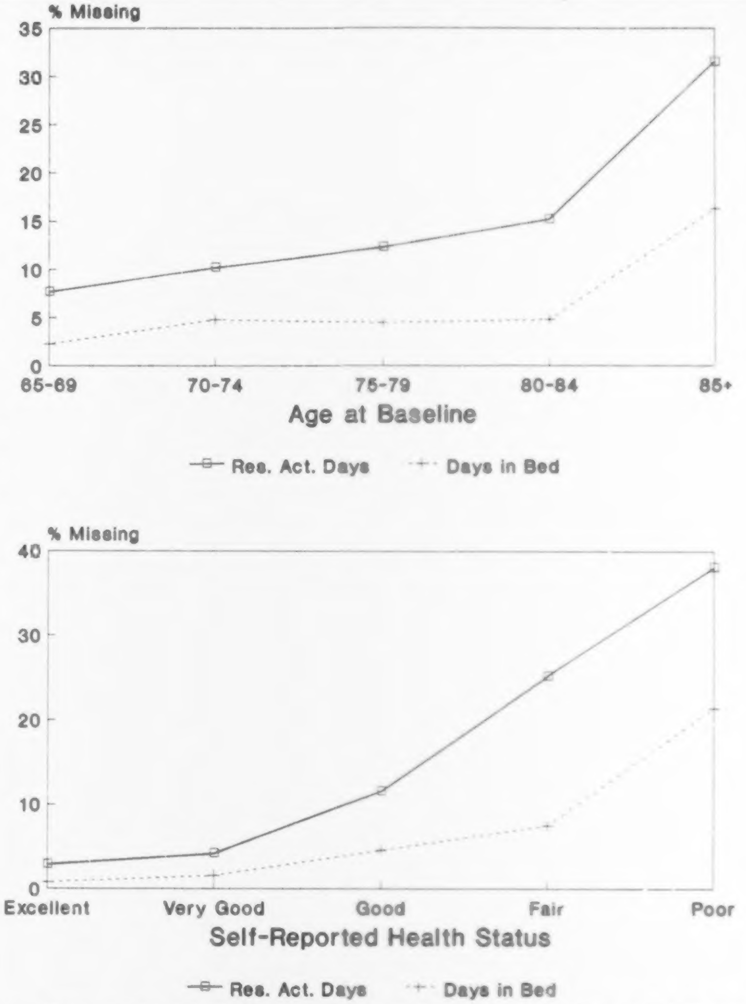

FIGURE 1—Rate of Missing Data for Restricted Activity Days and Days in Bed by Age Group and Self-reported Health Status

Discussion

The vague nature of RAD has been cited as a drawback to its use.[7] Our findings indicate that the potential shortcomings do not preclude its use in studies where physical disability is the health dimension of interest. The validity of using RAD is supported by its being most highly correlated with measures of physical health status and with functional limitation measures in particular.

Our results do not support the suggestion that bed days may be a better indicator of physical disability; its correlations with virtually all other health status measures were weaker than those for RAD.

While these results support our initial hypothesis, several limitations to the use of RAD deserve mention. Both disability days variables had very skewed distributions in this sample of essentially well elderly, limiting their usefulness in describing the full range of physical health status. In addition, over 10 percent of the data on RAD were selectively missing, an indication that this variable, in self-administered form, posed problems for participants.

The proportion of the sample that agreed to participate in this study represents a potential limitation of this analysis. This would be particularly so if non-participants were more disabled than those who agreed to be part of the study. Our study of nonparticipants allowed us to replicate this analysis in part and provided information that they had similar levels of disability and similar correlation patterns.

As evaluation of the 1990 national

Risk Communication Activities ~~of~~ State Health Agencies

Caron Chess, MS, Kandice L. Salomone, MS, and Peter M. Sandman, PhD

ABSTRACT

Surveys concerning the risk communication practices and needs of state health agencies were completed by agency commissioners and designated staff of 48 states and territories. These data indicate that agencies are expending more effort on responding to requests for information than on initiating dialogues with interested constituencies or alerting the public to risk. The data also suggest a gap between the stated philosophy and practice of the agencies. (*Am J Public Health* 1991; 81:489–491)

Introduction

Increasingly, government agencies have been concerned about how to communicate environmental health risks to the public. There is a growing literature prescribing how agencies should practice risk communication,[1–4] describing case studies of agency efforts,[5–9] and investigating public perception of risk.[10–13]

Nevertheless, little is known about the risk communication activities and needs of public health agencies. We report briefly the results of a national survey of state health agencies. Two detailed reports, one dealing with the data's implications for risk communication training and the other dealing more fully with analyses of state health agencies' risk communication activities, are available from the authors.

Methods

Early in 1989, the Association of State and Territorial Health Officials (ASTHO) distributed a risk communication survey (developed by the Rutgers Environmental Communication Research Program) to the health commissioners of the 50 states, five territories, and the District of Columbia. The survey was developed primarily to assess health agencies' risk communication needs. Therefore, the questions focused solely on risk communication rather than on the broader context of respondents' responsibilities, priorities, and resources. Health commissioners were asked to complete one survey themselves and to designate one person with technical background and one with communication background to complete individual copies of a similar survey. The surveys elicited returns from 128 respondents from 48 states and territories, with the 85 staff respondents accounting for 66.4 percent of all data analyzed and 43 commissioners accounting for 33.6 percent of analyzed data. Returned surveys reflect a 76.8 percent response rate for commissioners and a 75.9 percent response rate for agency staff.

Results

According to staff respondents, the five environmental health issues on which agencies devoted the most time to communicating with the public in the past year were: drinking water contamination (90.6 percent); radon in indoor air (64.7 percent); potential cancer clusters (62.4 percent); clean up of hazardous waste sites (57.6 percent); and pesticides (43.5 percent).

The dominant risk communication activity of agency staff is responding to inquiries (mean percentage of time = 62.1 percent). The remaining time is split between designing and planning outreach activities to alert the public to environmental health risks (21.8% percent) and soliciting input from the public on agency policies and actions (12.7 percent).

Staff reported that their agencies communicate on a daily basis with individuals who contact them with questions about environmental issues, but they initiate contact only about once a week. They talk only once or twice a month with environmental advocacy groups, other groups that address specific environmental issues, and neighborhood community groups.

When responding to inquiries, staff reported that the people with whom they speak most frequently have learned about a potential risk from the media and that they deal most frequently with people who have emotional responses to risk (Table 1).

When soliciting input from people outside the agency on agency policies and environmental health issues, staff reported that their agencies used telephone contacts and informal meetings more frequently than seven other sources of input

Mass mailings	1.52	0.85	1.00

[a] Descriptive statistics were calculated from a five-point Likert-type scale where (1) indicated an answer of "seldom or never," (2) indicated an answer of "monthly," (3) an answer of "weekly," (4) an answer of "daily," and (5) indicated an answer of "constantly."

(Table 1). However, no single approach was used very often—perhaps a few times a month, at most.

Much the same can be said for the frequency with which agencies conduct activities to alert the public to potential environmental hazards. Across 14 different methods, the most any one method was practiced was a few times a month. Most methods were used monthly and a few were used less than once a month (Table 1).

We probed agency philosophy with 10 statements. More than two-thirds of all respondents either "agreed" or "strongly agreed" with the following five statements:

- "communicating with the public about environmental risk is an important agency priority" (90.6 percent);
- "risk communication training is important to improve agency efforts" (87.3 percent);
- "a major barrier to effective environmental risk communication is public misunderstanding" (82.4 percent);
- "a major barrier to environmental risk communication is insufficient training for new and existing staff" (75.8 percent); and
- "a major barrier to effective environmental risk communication is insufficient staff for risk communication" (67.2 percent).

More than two-thirds of all respondents either "disagreed" or "strongly disagreed with these two statements:

- "communicating with the public about environmental issues does not make much of an impact" (88.2 percent); and
- "better to communicate less than to risk stirring up problems" (76.4%).

More than half "disagreed" or strongly disagreed with

- "the public should be encouraged to leave risk management decisions to the professionals" (57.1 percent).

Discussion

These data suggest that agencies, in spite of their philosophical commitment, are expending more effort on responding to requests for information than on initiating dialogues with interested constituencies or alerting the general public to risk.

Most agency efforts are devoted to responding to inquiries from the public, and most inquiries from the public are generated by the media. Although respondents indicated that their agencies spent more than 20 percent of their communication time on outreach activities, they reported using most outreach methods—including contacting the media—fairly infrequently (monthly or less), again suggesting that they may be reacting to communication events rather than shaping them.

The majority of respondents disagreed with the statement that the public should be encouraged to leave risk management decisions to the professionals, but no methods to solicit input were used with any frequency. This may indicate the flexibility that is important when dealing with a variety of audiences, or it may suggest that little time is spent in soliciting public input and even less in developing plans and policies on how to solicit input. ☐

Acknowledgments

This research was funded by a cooperative agreement between the Agency for Toxic Substances and Disease Registry (ATSDR) and the

Association of State and Territorial Health Officials (ASTHO) which subcontracted the development, analysis, and interpretation of the survey to Rutgers University's Environmental Communication Research Program. The authors are grateful to ASTHO, ATSDR, and the Public Health Foundation (PHF) for their input into the development of the survey; to ASTHO for distributing and collecting the surveys; and to the PHF for tabulating the data. We also appreciate the assistance of Billie Jo Hance, who had considerable input into the development of the survey, and David Holtgrave, who advised us on methodology. The opinions expressed in this article are those of the authors alone.

Capacity of US Labs to Provide TLI in Support of Early HIV-1 Intervention

Ronald O. Valdiserri, MD, MPH, G. David Cross, MS, A. Russell Gerber, MD, Robert E. Schwartz, BS, and Thomas L. Hearn, MS

ABSTRACT

We surveyed laboratories to assess their capacity to perform T-lymphocyte immunophenotyping. Of the 1026 respondents, 279 located in 41 states and the District of Columbia performed this type of testing. Most laboratories were located in hospitals, reported a low weekly test volume, and indicated that it took 6–24 weeks for flow cytometer operators to become proficient. Many laboratories appear to have the capacity to perform additional CD4+ cell testing, but training additional operators may be necessary. The paucity of laboratories performing T-lymphocyte immunophenotyping in the public sector may affect referral patterns from that setting. (*Am J Public Health* 1991;81:491–494)

Introduction

In 1989, the US Public Health Service recommended that all persons infected with human immunodeficiency virus type-1 (HIV-1) have CD4+ cell counts performed at least every six months.[1] This recommendation is based upon the knowledge that CD4+ cell counts are a major predictor of disease progression in HIV-1 infection,[2] and that information provided by this test is used to make therapeutic decisions about initiating antiretroviral therapy and prophylactic therapy for *Pneumocystis carinii* pneumonia.[3] Because CD4+ cell counts are currently performed by flow cytometric analysis, a technique that is not commonly used in many laboratories, a survey was conducted by the Division of Laboratory Systems, Public Health Practice Program Office (PHPPO) of the Centers for Disease Control (CDC) to learn more about the national availability of this testing and about testing practices in the laboratories currently providing CD4+ cell testing services.

Methods

In August 1989, 1,658 laboratories were surveyed to learn more about their T-lymphocyte immunophenotyping (TLI) testing practices; 1,348 were currently enrolled in a voluntary HIV-1 antibody testing performance evaluation program conducted by the CDC,[4] and 310 were enrolled in a flow cytometry proficiency testing program sponsored by the College of American Pathologists (CAP). The sur-

*Does not include missing or incomplete data; therefore, N may be smaller than total sample.

veys, which were identical, were mailed independently. Laboratories that may have received one from both sources (i.e. enrolled in both programs) were requested to respond to the CDC survey only. Prior to data entry, obvious duplicate surveys (i.e. same laboratory name and address) were removed. After data entry, additional duplicate surveys were detected by examining for identical survey responses, across mailings, for laboratories which had the same postal zip codes; duplicate responses were removed from the data base. A total of 1,026 unduplicated surveys were available for analysis: 908 were from laboratories enrolled in the CDC-funded program and 118 were from laboratories which were enrolled in the CAP program, but not in the CDC program.

Results

TLI was performed by 279 (27 percent) of the laboratories, 116 from the CAP program and 163 from the CDC program. Information available on 734 of the 747 respondents not currently performing TLI testing indicated that 12 percent were considering providing this type of testing on-site within the next 12 months. Currently, 45 percent of the laboratories not performing TLI on-site offer the test through referral—most often (70 percent) to a commercial laboratory.

Table 1 shows the percentage distribution of laboratories performing and not performing TLI, by type, for the 1,026 laboratories returning surveys. Non-blood bank hospital laboratories (relative risk [RR] = 2.1; 95 percent confidence interval [95% CI]: 1.8, 2.5) and research laboratories (RR = 4.1; 95% CI: 2.1, 8.2) were more likely to perform TLI testing and health department laboratories (RR = 0.1; 95% CI: 0.04, 0.3) and blood banks (RR = 0.4; 95% CI: 0.3, 0.5) were less likely to do so.

TLI testing laboratories were located in 41 states and the District of Columbia, with the states of California, Texas, New York, Ohio, Pennsylvania, and Florida representing 39 percent of all TLI testing laboratories responding. Comparing the distribution of TLI testing laboratories by state to that state's AIDS rate for May 1989–April 1990,[5] a positive correlation was noted (Spearman rank correlation coefficient = .39, $p < 0.01$). Eighty-three percent of the laboratories reported that they tested specimens from an "off-site" location, i.e. not collected within the institution providing care.

In general, laboratories reported a low weekly testing volume (Table 2). Sixty-three percent of all respondents reported testing fewer than 50 samples per week and 38 percent of that group actually tested fewer than 10 samples weekly. High-volume testing (>500 samples per week) was noted in 15 percent (9/62) of independent and research laboratories—more frequently than in the 5 percent (10/211) of other types of laboratories (RR = 3.1; 95% CI: 1.3, 7.2).

Of those laboratories performing TLI testing, 82 percent had been testing for more than one year and 18 percent for one year or less. Not surprisingly, laboratories that have been performing TLI longer had higher weekly testing volumes. Forty percent (91/227) of laboratories that have performed TLI longer than one year tested 50 or more samples per week compared with 20 percent (10/49) of laboratories that have performed TLI one year or less (RR = 2.0; 95% CI: 1.1, 3.5).

When questioned about their routine sample staining protocol, some laboratories reported using more than one protocol, but most laboratories (75 percent) reported that their routine sample staining protocol was to stain whole blood samples, then lyse red blood cells. Eleven percent reported that they lyse red blood cells first and then stain samples, and 22 percent reported that they stain the sample after mononuclear cells have been separated by density-gradient centrifugation. When asked what cell markers were included in the normal battery of tests performed on each patient sample, the following observations were noted: CD4 (99%); CD8 (99%); CD3 (75%); CD2 (62%); CD19 (50%); CD20 (42%); CD45 (38%); DR (28%); CD14 (26%); NKH-1 (24%); CD57 (13%); 4B4 (11%); and Leu 19 (11%). The reported frequencies for other cell surface markers were less than 10 percent.

Self-reported quality assurance practices indicated that 97 percent of the laboratories had written protocols for specimen collection; 98 percent had protocols for routine calibration of their flow cytometers; and most (87 percent) performed instrument calibration daily. Ninety-one percent of laboratories performing TLI participated in an external proficiency testing program.

When questioned about the sources of training for persons performing TLI, the two most ~~frequent~~ types of training reported were instrument manufacturer's training school (84 percent) and in-house (83 percent). However, 48 percent of TLI laboratories reported taking advantage of courses offered by universities, professional societies, and industry (other than the instrument manufacturers). When questioned about the length of time needed for flow cytometer operators to become proficient in performing TLI testing, the responses range from one-to-five weeks to greater than 18 months—although 55 percent reported a range of six-to-24 weeks. Fifty-four percent (121/225) of the laboratories with longer than one year of TLI testing experience reported that four months or more were needed for the operator to become proficient, while only 31 percent (15/49) of the laboratories with a year or less testing experience reported that this same level of experience was required to successfully perform TLI (RR = 1.8; 95% CI: 1.1, 2.7).

Discussion

Early medical intervention in HIV-1 infection marks a new phase in our experience with the epidemic of acquired immunodeficiency syndrome (AIDS) in which efforts to prevent the spread of HIV-1 through counseling and testing will become integrated into medical treatment and case management. In addition to the obvious medical benefits of improving the health and longevity of infected persons, it has been suggested that early treatment programs targeted to persons who are already infected with HIV-1 might significantly augment current prevention efforts by providing further opportunities for behavioral intervention, thereby resulting in decreased viral transmission to others.[6]

To achieve the goal of providing appropriate and timely medical and psychosocial services to all individuals who are infected with HIV-1, it will be necessary to ensure that the capacity for service exists and that adequate delivery systems are in place. A 1989 policy analysis of the impact of Public Health Service recommendations for prophylactic treatment of *Pneumocystis* pneumonia indicated that "State, regional, county, and city governments will need to coordinate and plan" for the provision of health services required to support these recommendations.[7] This planning must encompass all relevant health care disciplines, including the laboratory which plays a critical role in the diagnosis and prognostic assessment of persons infected with HIV-1.

Because recommendations for both antiretroviral therapy and *Pneumocystis* prophylaxis are based upon the level of CD4+ cells in the peripheral blood, this laboratory test plays a critical role in early intervention efforts. The provision of CD4+ cell testing services to support early HIV-1 intervention efforts will require: adequate instrument capacities, adequate numbers of trained laboratory personnel, access (either direct or through referral) to CD4+ cell testing services by health care workers providing care to HIV-1 infected persons, including those at counseling and testing sites, and financial resources to support this service, especially for indigent persons who are HIV-1 infected.

This survey indicates that many laboratories across the nation are already performing CD4+ cell testing, and laboratories appear to have the capacity to perform additional testing. Obviously, our survey does not include all of the laboratories currently performing CD4+ cell testing. At the time this survey was conducted, we estimate that nearly 1,000 laboratories were performing CD4+ cell testing by flow cytometry (personal communication: Jeffrey Johnson, Program Resources Inc). Therefore, our survey sample probably represents at least 30 percent of all laboratories currently performing this test.

Assuming financial resources are available, the ability to perform additional TLI testing is a function of both instrument and personnel capacity. According to experts in flow cytometry, it is estimated that one fully-trained person should be able to test at least 10 specimens (six markers per specimen) within an 8-hour period. (Personal communication: Dr. Janet Nicholson, Centers for Disease Control.) Although our survey suggests that there may be equipment capacity to accommodate additional testing, it is likely that new personnel will have to be trained to provide for these services. As such, it is interesting to note that laboratories with more experience in performing TLI tended to give longer estimates of time to achieve flow cytometer operator proficiency than those laboratories which have had less experience in the field. There are several probable reasons for the observed range of responses. Experienced laboratories may have older equipment that required more training to learn how to operate compared to newer equipment which tends to be more "user friendly." Also, laboratories with less experience in TLI testing may underestimate the time that it takes operators to become truly proficient in this procedure. And finally, experienced operators may realize that, even with newer equipment, operator training is requred to ensure that the equipment is providing valid results.

These findings should not be interpreted to imply that adequate capacity exists to provide all of the TLI testing needed, only that instrument capacity exists to perform additional testing. The exact need for this testing is still not known, but will depend upon the number of HIV-1-infected persons and the stage of their illness. Untreated individuals who have been infected for longer periods will experience a more rapid decrease in the CD4+ count[8] and may therefore require TLI testing more frequently than twice yearly.

It is apparent from this survey that many of the laboratories which have capacity to perform additional TLI testing are not located in departments of public health. Therefore, bringing together counseling and testing services with medical treatment for early intervention will require a close coordination of services between the entry level of identifying persons who are infected with HIV-1, much of which takes place in the public sector, and the subsequent medical evaluation and provision of care which often takes place in the private sector. Efforts to prevent secondary morbidity and mortality by implementing early HIV-1 intervention programs will involve the assurance that reliable CD4+ cell testing services are available, either directly or through referral, to health care providers treating HIV-1 infected persons.

When HIV-1 counseling and testing takes place in a physician's office, individuals who are found to be infected can be further evaluated or referred for evaluation to determine whether the degree of their immunodeficiency, as determined by CD4+ cell testing, warrants antiretroviral therapy[9] and/or prophylactic therapy to prevent *Pneumocystis carinii* pneumonia.[1] However, considering that less than 4 percent of the publicly funded HIV-1 counseling and testing provided between January 1988 and September 1989 took place in private physician's offices and clinics,[10] it is unlikely that this scenario will apply to the majority of persons who are found to be infected with HIV-1.

Between January 1988 and September 1989, it is estimated that freestanding HIV-1 counseling and testing sites and clinics for the treatment of sexually transmitted diseases (STD) accounted for 65 percent of all publicly funded HIV-1 counseling and testing and 69 percent of all positive tests.[10] One way to ensure that HIV-1 infected persons identified by these programs have physical access to necessary CD4+ cell testing services is by developing a case-management system in which case managers are dedicated to coordinating and monitoring the referral of HIV-1 infected persons into systems which provide medical evaluation and, where appropriate, treatment.

Another option is to expand the provision of TLI testing in the public sector. Participants at the Fifth Consensus Conference on Testing for Human Retroviruses, hosted by the Association of State and Territorial Public Health Laboratory Directors, recommended that "State and local public health laboratories should be making plans immediately for provision of flow cytometric measurement of CD4+ cells" (Fifth Consensus Conference on Testing for Human Retroviruses, March 1990). Some states have already begun to explore this possibility,[7] although it may be practical only in those states with a large number of HIV-1 infected persons. Because storage time and temperature of the specimen may affect T-lymphocyte counts,[11] problems arising from specimen transport to distant sites may limit the degree to which this service can be centralized. Other states may opt to contract with independent commercial laboratories or with local laboratories in tertiary care facilities for the provision of high-quality TLI testing to HIV-1 infected persons.

Many of the concerns about provision of CD4+ cell testing would be minimized by simpler, less costly, tests. Although a number of other biologic markers have prognostic implications in persons infected with HIV-1, none to date have been shown to be superior to CD4+ cell enumeration.[2,12] Therefore, it is unlikely that CD4+ cell testing will soon be replaced as the major source of laboratory information about when to initiate therapy in persons with HIV-1 infection.

Regardless of the approaches taken, implementing early intervention activities by bridging the gap between identifying HIV-1 infected persons and providing medical care to these persons will involve the allocation of additional resources to provide the necessary laboratory services. It is unlikely that private insurance alone will be able to finance the laboratory services needed to achieve early intervention for all HIV-1 infected persons, thus public sector support may be needed. ☐

Response of Hospitals, Skilled Nursing Facilities, and Home Health Agencies in Oregon to AIDS: Reports of Nursing Executives

Caroline McCoy White, DrPH, and Marie C. Berger, PhD

ABSTRACT

To describe experience and readiness to provide care for persons with acquired immunodeficiency syndrome (AIDS), responses to a mailed survey from 86 percent of chief nursing executives of the 207 hospitals, skilled nursing facilities (SNFs) and home health agencies (HHAs) in Oregon were summarized. As of January 1989, 44 percent reported having provided care; even in low incidence counties, 64 percent of hospitals had provided care. Adequate resources were reported by 79 percent in hospitals, 26 percent in SNFs, and 69 percent in HHAs. (*Am J Public Health* 1991;81:495–496)

Introduction

Developing resources for providing care to persons infected with the human immunodeficiency virus (HIV) or having acquired immunodeficiency syndrome (AIDS) is a societal concern. In Oregon, while the incidence of AIDS is not high on a per capita basis (697 cases reported by December 31, 1989 and a population of 2,687,000[1]), there is a significant and growing population for whom services must be provided. It challenges all health care institutions in Oregon.

Because nursing care is a critical component of the services that persons with AIDS require, we wanted to ascertain the extent to which agencies providing nursing services had cared for persons who had AIDS; and identify factors inhibiting care of AIDS patients. Chief nurse executives (CNEs) were selected as informants because they are responsible for developing policies and allocating resources for nursing care; they are also influential in the decisions made in their agencies.

Methods

In January 1989, we mailed questionnaires to CNEs of all hospitals (n = 79), skilled nursing facilities (whether or not hospital-associated, n = 66), and home health agencies (whether or not hospital-associated, n = 62) licensed and located in Oregon. The questionnaire probed the agency's current experience with providing care and resources to care for persons with AIDS; the overall impact of the epidemic on the agency; and the future role of the agency as perceived by the CNE. The questionnaire had both a prescribed format for response and opportunities for comments. After the second mailing and telephone follow-up, and eliminating the blank questionnaires, the over-all response rate was 86 percent. The CNEs whose responses were used for analysis represent 97 percent of hospitals, 76 percent of skilled nursing facilities, and 84 percent of home health agencies in Oregon. They include 81 percent of the 100 agencies (95 percent of hospitals, 77 percent of SNFs and 67 percent of HHAs) in high prevalence areas (defined as those counties where cumulative numbers of reported cases were 11 or more as of December 31, 1988[2]) and 92 percent of the 107 agencies (100 percent of hospitals, 74 percent of SNFs and 95 percent of HHAs) in low prevalence areas.

Results

Even though Oregon has a moderate prevalence rate for AIDS (251.6 cases per million population in 1989[1]), in early 1989 44 percent of the 207 agencies reported having provided care for persons with AIDS (Table 1). This includes 89 percent of the hospitals and 81 percent of HHAs in high incidence areas, but only 8 percent of the SNFs regardless of location. Even in low incidence counties, 64 percent of hospitals had provided care to persons with AIDS.

CNEs were asked to check specific agency resources for the care of AIDS patients and implementation of universal precautions (Table 2). As a group, CNEs of hospitals reported relatively more resources for supporting care than did those of either the SNFs or home health agencies. More resources were reported for agencies in high incidence areas.

In order to identify factors inhibiting provision of care to persons with AIDS, a list of nine items was presented. The four most frequently cited are shown (Table 2). Proportionately more CNEs of SNFs indicated that these factors were relevant in their situations.

In response to forced choice options to describe the impact of the epidemic, at

Current Issues Inhibiting Care of AIDS Patients						
Confidentiality	16	22	13	13	2	11
Inadequate reimbursement	3	10	11	11	5	6
Lack of resources for staff education	2	5	5	3	2	8
Staff, patients & families might shun agency	0	3	14	15	1	5

[a] On basis of cumulative number of reported cases by county of residence at onset of symptoms (low = 10 or less; high = 11 or more) (Ref. 2).

least 40 percent of CNEs in each agency group reported that the epidemic had little or no effect on their agencies. Comments reflected the basis for judgement about low impact: either the agency had not provided care to persons with AIDS or their numbers had been few. However, other comments noted the extensive effort required for writing and implementing policies and procedures for universal precautions.

In assessing anticipated future roles of agencies in response to the epidemic, CNEs of 29 percent of hospitals, 18 percent of SNFs and 37 percent of HHAs anticipated that their agencies would be "at the forefront." This perception was reported by proportionately more CNEs from high prevalence areas where anticipation of being in the forefront was reported by 35 percent from hospitals, 27 percent from SNFs and 46 percent from HHAs.

Discussion

If the Oregon experience is generalizable, agencies in low incidence areas in moderate and low incidence states should expect to provide care for persons with AIDS. And, if SNFs are to be future resources for care for persons with AIDS, the responses of CNEs in these facilities suggest that a concerted effort is needed to market the idea to their sponsors; the fears they expressed point to the need for further community education and involvement.

These data should alert policy-makers about preparedness for providing nursing services to persons with AIDS. At all levels policy-makers must develop a new spectrum of coordinated services across agencies that provides support to nursing care with "models that are effective and attractive to both patients and nurses."[3] ☐

Mass Flea Outbreak at a Child Care Facility: Case Report

Larry D. Corpus, PhD, and Kathleen M. Corpus, PhD

ABSTRACT

Cat fleas, *Ctenocephalides felis* Bouchet, were collected at a Mississippi child care facility after reports of large numbers of adult fleas occurring on children and personnel. One building yielded 161 (99 percent) of the fleas collected. Urticarial lesions due to flea bites occurred on the legs of six children. Flea presence was due to cats occupying the crawl space. Fleas were eradicated by eliminating entry of cats and using residual insecticides throughout the facility. (*Am J Public Health* 1991;81:497–498)

Introduction

Cat fleas, *Ctenocephalides felis* Bouchet, are common obligatory ectoparasites, often evident in homes where pets are kept. Their role in host annoyance and disease transmission is well documented.[1] Mass emergence of adults can occur if population numbers are suitably high and environmental conditions are optimal.[1,2] Outbreaks are rarely noted in the literature, although several entomologists consulted could recall anecdotal occurrences of mass flea emergence. In this paper, we report on a case which occurred at a child care facility in northeast Mississippi.

Methods and Results

Case Report

The child care facility occupies two buildings separated by a playground. Children 6 months to about 3 years of age occupy Building 1; children 3 to 4 years of age use Building 2. Both buildings date from the 1940s and were originally private homes constructed of wood clapboard set upon brick walls surrounding conventional foundations. Plumbing and air handling systems are in crawl spaces with access through doors below exterior stairways.

On July 25, 1988, several children from Building 2 entered the playground. One child returned almost immediately screaming that fire ants were crawling on her legs and biting her. Fire ant mounds had been removed from the playground on several occasions. About 50 insects were estimated to be on the child's legs, and were believed at first to be fire ants. However, when the director brushed the insects off and noticed that they "hopped" onto her arms and that similar insects were on her own pant legs, she concluded that they were fleas rather than fire ants. At the same time, four other children ran to the stairs from the playground indicating that they too, had "fire ants" and "bugs" on their legs and were being bitten. As many fleas as possible were removed from the children and everyone went indoors. A pest control company was contacted, but the premises were not treated until the following day.

On July 27, a maintenance worker entered the crawl space under Building 2 to perform routine equipment maintenance, and was later noted sitting on the outside stairs brushing fleas off his uniform. On July 28, reports were received from parents of children about fleas in their homes "biting everyone."

Physical evidence of flea bites was reported after August 2. Six children showed advanced cases of ulcerative sores on their legs, with the number of bites ranging from one to four per leg. Four of the six children exhibiting flea bites were in the initial group which entered the playground on July 25. Most children were not affected since facility personnel chose to remain indoors from July 25 to August 12, a period of 14 days. No adults reported any lasting effects of flea bites beyond brief itching around their ankles and knees. Only one child from Building 1 exhibited any flea bite symptoms, bearing a group of three urticarial lesions on the inside of his right ankle.

The senior author, notified of the flea problem on August 4, visited the site on August 5. Personnel were interviewed and collection of fleas initiated. While standing in the playground, 35 adults fleas were removed by aspiration from pant legs and socks. It was discovered that only a narrow band around each building had been sprayed with chlorpyrifos by the pest control company on July 26. On August 12, after all children, parents, and personnel had left the premises for the weekend, the entire facility was treated with propetamophos (Safrotin) and precor indoors, propetamophos and chlorpyrifos outdoors including the playground, and diazinon dust throughout the crawl spaces.

Adult fleas were removed from clothing and placed into 70 percent ethanol. Litter samples were taken from under each building and throughout the playground and berlesed (heat extraction) for

TABLE 1—Numbers of Adult and Larval (in parentheses) Fleas Collected from Building 2

	Collecting Method		
Date	Berlese	Dry Ice	Aspiration
Aug 5	-	-	35
Aug 8	5 (5)	2	43
Aug 10	17 (8)	4	21
Aug 15	8 (2)	1	7
Aug 17	0 (1)	0	2
Aug 19	0	0	0
Aug 22	0	0	0
Aug 24	0	0	0
Aug 26	0	0	0
Total	30 (16)	7	108

two weeks. Dry ice in white enamel pans was placed in the crawl spaces below each building. Continued collection and monitoring of fleas occurred until August 26 even though no fleas were detected in any stage after August 16.

Identification of the fleas indicated that they were cat fleas, *Ctenocephalides felis* Bouchet (Siphonaptera:Pulicidae). The number of fleas collected from Building 2 for the period August 5 to August 26 are shown in Table 1. Adult fleas comprised the majority of individuals collected (90.2 percent), whereas larvae, all from the crawl space, accounted for only 9.8 percent of the total. Only two adult fleas were collected adjacent to Building 1. The disproportionate number of flea larvae and adults collected from Building 2 suggests that adult fleas were originating from below Building 2. Both the maintenance worker and the senior author attracted fleas while under Building 2, but not while under Building 1. Most of the fleas (98.6 percent) were collected during the first four collecting dates. No flea pupae were collected.

Discussion

The most probable explanation for the greater number of fleas around Building 2 was the presence of several cats in the vicinity on several previous occasions and their continued use of the crawl space. Cats from surrounding buildings roam freely during the day and night and had been trapped near Building 2 on several previous occasions. Fur, feces, and masticated rodent remains below Building 2 further attested to the presence of cats. Cats had entered through open vent holes in the foundation and occupied the crawl space so that eventually a substantial population of fleas had built up. Since similar conditions did not exist at Building 1, very few fleas occurred near it.

Although *Ctenocephalides* spp. fleas have the potential to vector a number of diseases,[2,3] those collected in this case were not tested for pathogens. It was recommended that, in the future, better chemical control measures be used in a more timely manner and that all openings into the crawl spaces below each building be closed off with at least a fine mesh screen. We further suggested that trapping of free-ranging pets be continued, and leash ordinances be enforced in order to reduce or eliminate potential flea hosts. □

Acknowledgments

Impact of Work on the Quality of Life of Community-Residing Young Elderly

Hirsch S. Ruchlin, PhD, and John N. Morris, PhD

ABSTRACT

Using a random sample of 310 Massachusetts community-residing elderly between the ages of 65 and 74, this study investigates the relationship between employment status and quality of life using a modified version of the Spitzer Uniscale QL index. The odds of reporting the highest quality of life rating, after controlling for socioeconomic and health characteristics, was 3.51:1 for those who worked versus those who did not do so. (*Am J Public Health* 1991;81:498–500)

Introduction

A desire to work beyond the expected age of retirement has become more prominent in recent years.[1,2] Predictions of labor shortages and growing competition for those willing and able to work[3] has directed attention to the continued labor force participation of older people and to the potential reemployment of retirees. Maloney and Paul assert that greater opportunities to work could improve the quality of life for older people.[4] They note that nearly half of the nonworking adults between the ages of 55 and 64 reported that they would have preferred to continue working. Those who stopped work involuntarily said that they were less sat-

isfied with their lives than those who chose either to continue work or to retire.

Evidence to support the hypothesis that work has a positive impact on the elderly's quality of life is limited. Most of the literature focuses on whether retirement leads to increased mental health problems.[5-12] One study conducted by Soumerai and Avorn adopted an employment rather than a retirement focus.[13] Based on a sample of 55 individuals (25 experimentals and 30 controls) they report higher life satisfaction index scores for the experimental (i. e. work) group.

We report here a study of the relationship between employment and quality of life among those elderly who are most likely to be interested in working—those in the age group 65 to 74.

Methods

The Sample

Our data come from a representative sample of Massachusetts community elderly assembled by the Department of Social Gerontological Research, Hebrew Rehabilitation Center for Aged which spans the period 1982–87 (baseline n = 2,682). The sample was constructed by: dividing the state into its 27 home care areas; stratifying areas by size (small, medium, and large) and randomly selecting cities and towns from each area; and randomly selecting for each selected area residents 60 years of age and older from within two age strata (under 70 and 70 and over) from the state census. Data in the sample were obtained through telephone interviews.

The analysis in this study is limited to 1987 data and to individuals under age 75 in 1987 (n = 351). Individuals not in a community setting (n = 24) or who never worked (n = 17) were excluded, leaving a study sample of 310 people: 77 employed (24.8 percent) and 233 (75.2 percent) not employed. The mean age of these two groups was 69.8 years (SD ± 2.3) and 70.3 years (SD ± 2.3). Among those employed, 21 (27.3 percent) worked full-time and 56 (72.7 percent) part-time.

Study Variables

Quality of life, the study's dependent variable, was measured by a self-reported, broad-based, well-established measure—the Spitzer Uniscale QL index—using the scoring metric developed by Morris and Spitzer for use in a general community population. The Uniscale QL has been used with a number of different elderly populations including those with and without serious disabilities,[14,15] and has high interrater reliability and excellent validity properties when compared against other quality of life indicators.[14] It is described in Appendix A.

The independent variables used were: sex, marital status, a self-assessed overall health rating, functional status, a self-assessed rating of financial status, and work status. The coding of these variables and their descriptive statistics are reported in Appendix Table A2.

Results

Quality of Life Rating by Work Status

The distribution of quality of life ratings are reported in Table 1. Approximately 90 percent of the sample reported quality of life ratings in one of the two top categories. By work status, 85.7 percent of the working elders (95% CI = 77.9, 93.5) reported the highest quality of life rating compared to 57.1 percent of the nonworking elders (95% CI = 50.7, 63.5). Focusing on the two highest quality of life ratings, 96.1 percent of the working elders (95% CI = 91.8, 100) were in this range compared to 87.6 percent (95% CI = 83.4, 91.8) of the nonworking elders. No significant differences emerged in a separate analysis of quality of life ratings by extent of work (i.e. full- or part-time).

Impact of Work on Quality of Life

Logistic regression was used to assess the impact of the independent variables on the likelihood of reporting the highest quality of life rating of 7 versus ratings of 1 through 6. The odds ratios associated with each of these variables are reported in Table 2. Three variables display definite impacts—self-assessed health, functional status, and work status. Adjusting for other factors included in the analysis, the likelihood of an elderly person who is working either full-time or part-time displaying the highest quality of life rating is 3.51 times that of an elderly person who is not working.

Discussion

Two health-related factors emerged as associated with the highest quality of life profile: self-assessed health, and functional independence. Working also emerged as a very important element. While work produces extra income to supplement Social Security and pension or investment income, financial security per se was not a significant correlate of a very high quality of life profile. We suggest that the feeling of "usefulness" and "value" traditionally associated with having a job underlies the work-quality of life relationship reported here.

Our results, which clearly await replication from studies that span a broader geographic base and time horizon, indicate that efforts at improving the life of the growing number of "young elderly" (i. e. people in the 65–74 age range) encompass programs that help people over the age of 65 stay on their current job or find new employment that better meets their current needs and capabilities. Such efforts will contribute to the improved social and mental health of the elderly. ☐

APPENDIX

In its self-report version, Uniscale QL scores quality along a seven-category continuum based on a response to the following question: "How would you rate your overall quality of life? Think of a ladder with 7 rungs, where the first, lowest rung applies to someone completely dependent physically on others, seriously impaired mentally, unaware of surroundings, and in a hopeless position. At the top of the ladder, the 7th rung applies to someone physically and mentally independent, communicating well with others, able to do most of the things enjoyed, pulling one'sown weight, with a hopeful yet realistic attitude. Where would you place yourself on this 7-rung ladder?" The distribution of the self-report Uniscale QL index for a representative sample of community elders in Massachusetts is reported in Table A1.

TABLE A1—Uniscale QL Distribution for A Representative Sample Of Community Elders in Massachusetts (N = 1,582) (in percent)

		Extent of Functional Disability		
QL Rating	Total Sample	No ADL/IADL Deficit	IADL Deficit/ No ADL Deficit	ADL Deficit
1 (lowest)	0.8	0.1	0.3	11.2

7 (highest)	40.4	45.9	14.7	15.4
(% of sample)		(82.6)	(11.7)	(5.7)

TABLE A2—Coding of Independent Variables and their Descriptive Statistics

Variable	Coding	Mean	Standard Deviation
Sex	1 = Female 0 = Male	0.558	0.497
Marital Status	1 = Married 0 = Not married	0.600	0.491
Self-Assessed Health Status	1 = Excellent or good 0 = Fair or poor	0.781	0.414
Functional Status	1 = Independent 0 = Dependent[a]	0.919	0.273
Self-Assessed Financial Status[b]	1 = Good 0 = Fair or poor	0.687	0.464
Work Status	1 = Working 0 = Not working	0.248	0.433

N = 310 except for functional status where n = 309.

a) Dependent in either personal activities of daily living and/or instrumental activities of daily living.

b) Data for this variable were drawn from the responses to the following question: "Would you say that you have enough money to live on with little trouble, just enough to get by, or not enough to make ends meet?" These responses were characterized as good, fair or poor, respectively.

Black-White Differences in Cancer Prevention Knowledge and Behavior

Christopher Jepson, PhD, Larry G. Kessler, ScD, Barry Portnoy, PhD, and Tyson Gibbs, PhD

ABSTRACT

Data from the 1987 National Health Interview Survey Cancer Control Supplement were used to estimate multivariate logistic regression models of diet change, mammography utilization, stool blood test utilization, and smoking. Predictor variables included race, sex, age, income, dietary concerns, and four knowledge-related variables: education and three measures of cancer prevention knowledge. When knowledge variables were included in the models, race was not a significant predictor of behavior, with one exception: among women, Blacks were found to smoke less than Whites. (*Am J Public Health* 1991;81:501–504)

Introduction

Blacks have a higher incidence of and mortality from cancer than Whites.[1,2] This differential presumably reflects differences in demographic factors such as education and income, and cognitive psychological factors such as attitudes and knowledge which influence behavior.

Although studies have shown that Blacks tend to have lower levels of cancer knowledge than Whites,[3–5] the relationship between knowledge level and cancer-preventive behavior has not been adequately documented. Some studies indicate a relationship between knowledge and behavior,[6–9] while others do not do so.[10,11] At minimum, however, some basic preexisting level of knowledge is a prerequisite for any instrumental behavior. Theories such as the Health Belief Model,[12,13] PRECEDE,[14] and Fishbein and Ajzen's theory of reasoned action[15] also postulate a relationship between behavior and beliefs, which are presumably based upon knowledge to some extent.

In 1987 the National Health Interview Survey (NHIS)[16] included a Cancer Control Supplement assessing a variety of demographic and cognitive psychological factors in addition to cancer-preventive behaviors. This made it possible to examine the extent to which such factors were associated with Black-White behavioral differences.

Methods

A total of 22,043 adult respondents over the age of 18 provided data on the 1987 NHIS Cancer Control Supplement. To increase accuracy of point estimates, Blacks were oversampled: 3,053 respondents (13.9 percent of the total sample) described themselves as Black.

For the purposes of our analyses, the study population was restricted to respondents describing themselves as either Black or White; Hispanics and members of other ethnic or racial groups were excluded. This reduced the total number of respondents to 20,088. In the analyses reported here, the data are weighted (using weights assigned by the National Center for Health Statistics) so as to be representative of the US population.[16]

We selected four measures of cancer-preventive behavior as dependent variables. These variables are described in Table 1.

The independent variables selected for our analysis fell into two main categories—demographic (race, sex, income, education, age) and cognitive psychological (knowledge, belief, and attitude) measures. They are described in Table 2. A detailed description is provided in the Appendix.*

In our data analysis, we first examined Black-White differences in the dependent and independent variables, and then estimated logistic regression models of each dependent variable, using a special software program, RTILOGIT,[17] designed specifically for use on data sets of this type.

Results

Black-White Differences

Table 1 reveals substantial Black-White differences in rates of diet change, mammography, and stool blood testing; smoking differences are essentially confined to men. Table 2 shows that Blacks scored lower than Whites on the three knowledge measures and were less likely to believe that cancer is preventable.

Some independent variables, such as the knowledge measures, are continuous. Mean Black-White differences on these variables, shown in Table 2, appear small but when they are dichotomized and percentages are compared the differences are

TABLE 1—Distribution of Dependent Variables by Race[f]

Variable	Description	Race[a]		OR[b] (95% CI)
		Black (n)	White (n)	
Diet change	Self-report of whether respondent has "ever made any lasting and major changes in [diet] for health reasons"	31.3 (2971)	36.8 (17089)	0.78 (0.70, 0.87)
Mammography	Self-report of whether respondent has ever had a mammogram[c,d]	31.2 (907)	40.0 (5524)	0.68 (0.57, 0.81)
Stool blood test	Self-report of whether respondent has ever had a stool blood test[c,e]	31.3 (1448)	39.4 (9320)	0.70 (0.60, 0.82)
Smoking status	Self-report of whether respondent is currently a cigarette smoker	32.4 (2868)	28.7 (16521)	—
	Men only	37.8 (1020)	30.2 (7025)	1.40 (1.15, 1.71)
	Women only	27.9 (1848)	27.2 (9496)	1.04 (0.89, 1.20)

[a] Figures are percentages of Blacks and Whites reporting the given behavior. Respondents who describe themselves as Hispanic or as neither Black nor White are excluded.

[b] Odds ratio = odds of Blacks (vs Whites) reporting the given behavior.

[c] Respondents were first asked if they had heard of the given test. Those answering "no" or "don't know" were counted as never having had the test.

[d] Only women age 40 and over responded.

[e] Only men and women age 40 and over responded.

[f] Data are weighted to be representative of US population.

equal to or greater than those seen for the categorical variables.

Regression Analyses

In order to determine the extent to which knowledge-related factors could account for the relationships between race and cancer-preventive behaviors, we estimated two multivariate logistic regression models of each dependent variable. In the first or reduced model, all independent variables are included except for the four knowledge-related variables (education and the three measures of cancer prevention knowledge). The second or full model includes all of the independent variables in Table 2.

Table 3 shows the coefficients (betas) for all independent variables in the full models of the four dependent variables. The coefficients for race translate into the following odds ratios (i.e. the odds of Blacks reporting the given behavior compared to Whites): for diet change, 0.94 (95% CI = 0.84, 1.05); for mammography, 0.94 (95% CI = 0.77, 1.16); for stool blood test, 1.08 (95% CI = 0.91, 1.28); for smoking among men, 1.03 (95% CI = 0.83, 1.29); and for smoking among women, 0.71 (95% CI = 0.59, 0.85). Thus, in all models except that of women's smoking, Black-White differences in behavior do not persist when the other predictors are held constant.

Among women, race is not a significant predictor of smoking status by itself, as shown in Table 1. As Table 3 shows, however, Black-White differences become significant in the full model.

TABLE 2—Distribution of Independent Variables by Race[b]

Variables	Description	Percent in Population or mean value[a]		
		Overall	Black	White
Demographic Factors				
Race	% White	88.1	—	—
	% Black	11.9	—	—
Sex	% Male		44.9	47.7
	% Female		55.1	52.3
Education	Years completed, from 0 (none) to 18 (18 or more)		11.4	12.7
Age	Age in years		40.8	44.6
Square of age			—	—
Family income:				
% Under $10,000			27.1	11.2
% $10,000–$19,999			22.4	18.8
% $20,000–$34,999			20.8	27.3
% $35,000 & over			14.8	31.5
% Unknown			11.9	11.2
Cognitive Psychological Factors				
Fat & fiber knowledge	Maximum score = 8		3.65	4.79
Risk factor knowledge	Maximum score = 7		3.63	4.46
Cigarette risk knowledge	Maximum score = 5		3.62	4.12
Dietary concerns	Maximum score = 3		2.16	1.95
Belief that cancer is *not* preventable:				
% Agree/strongly agree			30.8	20.5
% Disagree			45.0	53.7
% Strongly disagree			9.5	16.9
% No opinion			14.8	9.0

[a] Respondents who describe themselves as Hispanic or as neither Black nor White are excluded. When percentages are given, the variable in question is a dummy variable; when means are given, the variable is continuous.

[b] Data are weighted to be representative of US population.

In the reduced models of each dependent variable, the betas for race are intermediate between those shown in Table 1 and those in Table 3, and all are significantly different from zero.

Discussion

Our results were generally consistent across all dependent variables except for smoking status among women. By includ-

**$p < .05$

***$p < .01$

ing knowledge-related variables in the analysis, Black-White behavioral differences were eliminated. In the case of women's smoking status, when other factors are controlled for, Black women become less likely than White women to smoke.

In addition to accounting for the effects of race, knowledge-related variables also displayed independent relationships with cancer-preventive behaviors. Education was a significant predictor in all models. Cigarette risk knowledge also contributed significantly in all cases, with its contribution greatest in the models of smoking status. Fat and fiber knowledge was a significant predictor of all dependent variables except smoking status; somewhat surprisingly, it was no more significant for diet change than for the other dependent variables. Risk factor knowledge contributed significantly only to the model of diet change.

The cross-sectional nature of the analysis places significant limitations on the conclusions to be drawn from this study. Associations discovered in such a study cannot be assumed to reflect causal relationships, and it is possible that other variables could account for Black-White behavioral differences as well as or better than the ones we chose to examine. Nevertheless, this study is unique in that it is the first national study assessing the independent effects of knowledge, beliefs, attitudes, and demographic factors on Black-White differences in cancer-preventive behaviors. The importance of cognitive psychological factors is indicated by the fact that even the imperfect measures available to us eliminated the behavioral differences.

Our findings suggest that a fuller understanding of Black-White behavioral differences can be gained by including measures of knowledge and attitudes, especially if these measures assess specific concepts directly related to the behaviors in question. Second, they suggest that there may be merit in investigating the use of interventions designed to narrow the behavioral discrepancies between Blacks and Whites by reducing the knowledge discrepancies. Longitudinal studies of this type should answer the question of whether enhancing cancer knowledge will result in increased cancer-preventive behaviors as a stepping stone to reductions in cancer mortality. ☐

APPENDIX

Description of Independent Variables

Reported family income was treated as a categorical variable rather than as an ordinal variable because approximately 12 percent of respondents did not provide income data. Respondents who did provide income data were divided into four categories, and each group was assigned a dummy variable; the unknowns served as the reference category.

Three measures of cancer prevention knowledge were created as follows: The first, *fat and fiber knowledge,* represents the number of correct answers to two questions in which respondents were given lists of foods and asked to identify which were sources of fat and fiber. The second, *risk factor knowledge,* was similarly created from an item in which respondents were asked to identify cancer risk factors. The third, *cigarette risk knowledge,* was taken from a set of five items in which respondents were asked to identify diseases caused by cigarette smoking. The reliability of this measure was very high (Cronbach's alpha = 0.90).

An attitude measure of dietary concerns was created from a set of three items in which respondents were asked if avoiding sodium, avoiding sugar, and lowering cholesterol were important concerns for them (alpha = 0.80).

Belief in the preventability of cancer was measured by degree of agreement with the statement, "There is very little a person can do to reduce his or her chances of getting cancer." Respondents were divided into four categories—those who agreed or strongly agreed, those who disagreed, those who strongly disagreed, and those with no opinion—with the last serving as the reference category.

Report of an Association between Race and Thyroid Stimulating Hormone Level

Joel M. Schectman, MD, MPH, Gene A. Kallenberg, MD, Robert P. Hirsch, PhD, and Ronald J. Shumacher, MD

ABSTRACT

We examined the association between race and thyroid stimulating hormone (TSH) level in 809 consecutive Black or White adults tested for mild suspicion of hypothyroidism with a normal TSH result. The mean TSH level of Blacks was 0.4 (SE .053) mU/L lower than that for Whites after age and sex adjustment, race explaining 6.5 percent of the variation in TSH levels. A validation sample yield similar results. This finding supports the possibility that differences in thyroid function and/or regulation may be associated with race. (*Am J Public Health* 1991;81:505–506)

Introduction

In two recent reports the incidental finding of an association between race and primary hypothyroidism has been noted.[1,2] The odds of both borderline and substantial thyroid stimulating hormone (TSH) elevations were greater among Whites than Blacks, controlling for age and sex. An increased risk of autoimmune thyroiditis among Whites has also been mentioned in thyroid textbooks,[3,4] but supported mainly by old hospital prevalence studies[5,6] with biases likely favoring detection of disease among Whites. Age and sex associations for primary hypothyroidism and autoimmune thyroiditis are well accepted, with previous studies documenting corresponding age and sex associations with TSH levels as well.[7-9] We hypothesized that a similar association would be found between race and TSH levels if there were a substantial racial association for hypothyroidism and autoimmune thyroiditis.

Methods

Subjects were consecutive adult primary care patients of the George Washington University Health Plan that had a TSH level for suspicion of hypothyroidism due to nonspecific symptoms or signs from April 1985 to March 1987. Patients on medications known to affect thyroid function tests or with a history of thyroid disease were excluded. Of 880 such patients identified, 33 were excluded due to an abnormal TSH level and 38 because either no race or one other than Black or White was noted in the medical record. This analysis is restricted to the remaining 809 Black or White patients tested for suspicion of hypothyroidism and found to have TSH levels within normal limits. Categorization of race was generally by patient self-report on the data base form in the chart. The racial demographics of this sample were similar to those of the entire health plan patient population.

The Magic TSH RIA (CIBA Corning Magnetic Immunochemistries, Medfield, MA) with normal limits of 0–5 mU/L was utilized for all TSH determinations obtained during the initial study period. A linear regression analysis was used to test for an association between race and TSH level. The model utilized TSH as the dependent variable, with age, sex, and race as independent variables, and chronic medical problems and/or medication use (both treated as dichotomous variables) as potential confounding factors. An analysis utilizing a log transformation of TSH to normalize the skewed distribution yielded similar results. Interactions between the independent variables were evaluated and a P-value of 0.10 or less was required to remain in the final model in a stepwise procedure.

In August 1989, a validation sample of 97 patients with normal TSH levels was collected at the study site by the same methods. The sample size was calculated to assure a 90 percent power of detecting a 0.4 mU/L difference in mean TSH levels at a 0.05 level of significance. The Magic mab TSH (CIBA Corning Magnetic Immunochemistries), an immunoradiometric sandwich assay with normal limits of 0.3–4.5 mU/L, was utilized for the TSH determinations on this patient sample. The analysis proceeded as described above.

Results

Of the patients from the initial study sample, 406 were Black and 403 were White. The interaction terms did not achieve a P-value of 0.10 or less and were thus eliminated from the final model. Chronic medical conditions and medica-

***Coded: Black = 0, White = 1.

tion use were not significantly associated with TSH levels. Age and race, but not sex, were independently predictive of TSH levels within the normal range (Table 1). Race explained 6.5 percent and age 0.8 percent of the variation in TSH levels. Whites had an age- and sex-adjusted mean TSH level 0.4 mU/L higher than Blacks.

Of the 97 patients in the validation sample, 51 were Black and 46 were White. The regression analysis again reveals an association between TSH level and race independent of sex and age. Race explained 5.5 percent of the variation in TSH levels with Whites having an age- and sex-adjusted mean TSH level 0.45 mU/L higher than Blacks.

Discussion

The present analysis reveals a racial association for TSH levels within the normal range in a population of primary care patients tested for generally mild suspicion of thyroid disease. The fairly large mean difference in TSH levels between Blacks and Whites in the two samples suggests that this association may be of clinical importance and is consistent with previously reported findings of a higher prevalence of borderline and frankly elevated TSH levels in Whites.[1,2] The association between race and TSH level was much stronger than that for age or sex, factors known to be associated with TSH level. An older sample would likely have demonstrated a greater age and sex dependency, however.

It is unlikely that these results are due to chance, given the highly significant P-value and the similar results obtained in the validation sample using the newer super-sensitive TSH assay.

It is possible that biased selection could account for these results since neither data set resulted from a random sampling of the population. This was necessary since, to our knowledge, no data base is available that contains race and TSH data for a normal reference population. However, for such a selection bias to have occurred, presumably euthyroid Whites with TSH levels higher in the normal range than Blacks (controlling for age and sex) must have been preferentially tested in both study samples. We are unaware of any reason for this to have occurred.

Several possible explanations of a racial association for normal TSH levels can be suggested. Environmental factors such as iodide consumption[4] might vary sufficiently between Blacks and Whites in the study population to affect thyroid function and account for the racial association. It is also possible that genetic factors differ between the Black and White patients tested and could account for a difference in TSH levels. Given previously determined relationships between race, gene frequency, and autoimmune disease,[10,11] such an association would not be surprising and has in fact been suggested by one study of post-partum thyroid dysfunction.[12] Population-based data are needed to confirm an association between race and thyroid function, as well as establish a link with antithyroid antibodies or other factors. Such information should be available from the NHANES III database in the future. ☐

Association of Waist to Hip Ratio and Family History with the Prevalence of NIDDM among 25,272 Adult, White Females

Robert D. Morris, PhD, and Alfred A. Rimm, PhD

ABSTRACT

The independent association of waist to hip ratio (WHR), relative weight, and family history with the prevalence of non-insulin dependent diabetes mellitus (NIDDM) was investigated in a population of 25,254 White females in the United States and Canada. A multivariate logistic analysis yielded standardized odds ratios of 1.47, 1.46, 1.54, and 1.14 for family history index, WHR, relative weight, and age, respectively. (*Am J Public Health* 1991;81:507–509)

Introduction

The association between obesity and non-insulin dependent diabetes mellitus (NIDDM) is well established.[1-3] More recent studies have demonstrated an association between the distribution of adipose tissue and NIDDM after adjusting for obesity and other risk factors.[4-11] The studies cited have used the ratio of waist to hip girth (WHR) as a measure of body fat distribution as first proposed by Rimm and Hartz.[4] The present study evaluates the independent associations of WHR, family history, relative weight, and age as they relate to the prevalence of NIDDM.

Methods

In 1969, TOPS (Take Off Pounds Sensibly), an organization of weight conscious women devoted to a responsible approach to weight control, sponsored the administration of an extensive health inventory to their members. The study yielded a total of 73,532 valid completed questionnaires from White females. Further details of the study design and the type of data collected are given elsewhere.[12,13]

Determination of the presence or absence of diabetes was based upon the subjects response of yes or no to the question, "Has a doctor ever said you had diabetes?" A study to assess the validity of the data, indicated that the medical information and anthropometric measurements supplied by the women was not biased by under- or overreporting.[14]

Only those women between the ages of 40 and 70 at the time of the study were included in the present analysis because the majority of cases of NIDDM appear in this age range. The exclusion of insulin dependent women resulted in a total of 25,272 White female subjects.

Weights and current girth measurements were self-reported. Relative weight taken as the ratio of actual weight to ideal body weight for height as given in the Metropolitan Life Insurance Tables[15] medium frame size served as an index of obesity. Relative weight ranged from 80 to 312 percent of ideal weight with a mean value of 1.32 and a median of 1.27. The ratio of waist to hip girth was used as the measure of body fat distribution.

The women recorded presence or absence of a number of diseases in their parents, grandparents, siblings, and children. This was used to calculate a family history index (FHI) for diabetes.[16] The following formula gives the index in terms of presence (= 1) or absence (= 0) of diabetes in the mother (M), the father (F), the brothers (B), the sisters (S), paternal grandparents (PGP), and maternal grandparents (MGP) of the subject.

$$\mathrm{FHI} = (M + F + B + S) + (PGP + MGP)/2.$$

Because of recent evidence associating smoking with increased WHR,[17] it was included in this analysis. Respondents were categorized as nonsmokers, light to moderate smokers, and heavy smokers based upon the number of pack-years smoked.

Subjects were divided into tertiles for WHR (<0.75, 0.75–0.80, and >0.80); they were divided into three groups for both FHI (0.0, 0.5–1.0, and >1.0), and for relative weight (<1.25, 1.25–1.50, and >1.50). This produced a $3 \times 3 \times 3$ matrix with 27 cells. Diabetes prevalence was determined for each of these cells.

Multiple logistic regression was used to evaluate the prevalence of diabetes as a function of age, family history index, WHR, relative weight, and all possible two and three way interactions. While this approach does not delineate interaction to

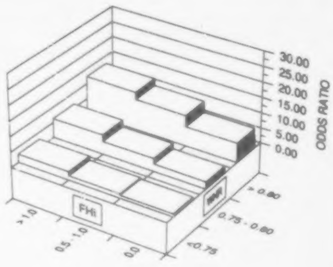

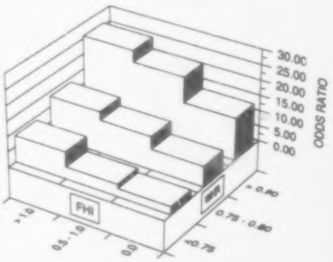

FIGURE 1a—Odds ratios for women between 25 and 50 percent above ideal weight with respect to women less than 25 percent above ideal weight at various levels of family history index (FHI), and waist to hip ratio (WHR) (1969 National Survey of Members of the TOPS Club, Inc)

FIGURE 1b—Odds ratios for women more than 50 percent above ideal weight with respect to women less than 25 percent above ideal weight at various levels of family history index (FHI), and waist to hip ratio (WHR) (1969 National Survey of Members of the TOPS Club, Inc)

the extent provided by calculation of odds ratios of interaction,[16] such an approach is impractical with this number of independent variables.

Results

Table 1 shows that the diabetic women were generally more obese, older, and had a higher FHI than the non-diabetic women. The Pearson correlation between relative weight and WHR was 0.26; WHR has a correlation with age of 0.20, but is only weakly correlated with family history of diabetes ($r = 0.04$).

Table 2 shows the steady increase in diabetes prevalence associated with increases in relative weight and family history. Prevalence rises from 1.4 percent for women in the lowest categories of WHR, relative weight, and family history to 26.5 percent for women in the highest risk group. Odds ratios increase consistently with WHR and family history when the two higher weight categories are compared to the lowest weight group (Figure 1).

Logistic regression results were standardized by calculating the odds ratios associated with an increase of one standard deviation in the independent variables (Table 3). The standardized odds ratio for diabetes associated with the family history index, WHR, relative weight, and age are 1.47, 1.46, 1.54, and 1.14, respectively. The only significant interaction was a standardized odds ratio of 0.94 for the combination of family history and relative weight. Smoking history was not significantly related to diabetes prevalence.

Discussion

The prevalence of diabetes increases with WHR at all levels of family history

TABLE 3—Multiple Logistic Regression Results for Diabetes Prevalence as a Function of Relative Weight, Family History Index (FHI) and Age and Their Interaction among Women from the 1969 National Survey of Members of TOPS Club, Inc*

†No other interactions were significant at the level, $p < .05$.

and similarly increases with increasing family history for the disease at each level of obesity, and both factors show independent associations with diabetes. These conclusions are supported by the logistic regression results.

An odds ratio less than 1 for the interaction of relative weight and FHI indicates that this interaction is less than multiplicative. No other interactions were significant. This implies that the associations between family history, WHR, relative weight, and age are multiplicative in nature.

Gestational diabetes and undiagnosed diabetes as well as other possible sources of bias such as those associated with variations in awareness of family history, the potential for weight change due to TOPS membership, and the possibility of weight gain or loss following the onset of diabetes apparently do not affect these findings.[16] If present, these biases would tend to reduce the strength of the observed associations. ☐

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription Price is $80/year US; $120/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Effects of an Intervention Program on AIDS-Related Drug and Needle Behavior among Intravenous Drug Users

Richard C. Stephens, PhD, Thomas E. Feucht, PhD, and Shadi W. Roman, PhD

ABSTRACT

Background: Behaviors which entail high risk for human immunodeficiency virus (HIV) infection among intravenous drug users can be significantly reduced through educational intervention.

Methods: The educational intervention was conducted by a health educator in a one-on-one format and provided information about acquired immunodeficiency syndrome (AIDS) and strategies for reducing the risk of infection. Risk was assessed prior to the intervention and was compared to a follow-up assessment obtained approximately three months later (n = 322).

Results: The percentage who reported using drugs intravenously decreased from 92.2 to 70.5, and the percentage who reported sharing syringes dropped from 67.4 to 24.3. Reductions of these and other high-risk behaviors were detected across various demographic subgroups, and analyses show that the impact of the intervention endured for several months.

Conclusions: The findings suggest that intravenous drug users conform to a model of rational choice when confronted with accurate information about the devastating consequences of HIV infection. (*Am J Public Health* 1991;81:568–571)

Introduction

Intravenous drug users (IVDUs) constitute the second largest group of persons with acquired immunodeficiency syndrome (AIDS) in the United States and serve as a major conduit of the human immunodeficiency virus (HIV) to other groups, including non-drug-using sex partners and their children.[1,2] Although interviews with successive waves of IVDUs entering drug treatment have suggested some stabilization of HIV seroprevalence as well as some reduction in high-risk behaviors such as sharing needles and the frequency of injection,* these patterns may simply reflect changes in the composition of successive cohorts of IVDUs. Based on repeated interviews with a sample of IVDUs, panel studies have demonstrated some reduction in the frequency of injection and the frequency of sharing needles,[3-5] but the extent to which the reduction of high-risk behavior is directly responsible for the apparent stabilization of seroprevalence rates remains uncertain.[6]

In the past few years, innovative risk-reduction interventions for IVDUs have been developed. Quasi-experimental studies used to evaluate the impact of these interventions have shown risk reduction among IVDUs including a decrease in the frequency of injecting drugs** and an increase in the use of bleach to disinfect shared needles.[7]

Quasi-experimental designs are not without drawbacks. Precautions must be taken to guard against small sample size and low follow-up rate. Since the design may not allow comparisons to any type of control group, other techniques must be used to resolve questions of internal validity. Furthermore, while interviews obtained at as few as two points in time provide the researcher with no direct means of confirming the stability of the change over time, certain data analytic techniques can be used to explore the issue of stability. Each of these drawbacks is addressed in this report in which findings are presented from a quasi-experimental evaluation of an intervention program designed to reduce the chance of HIV infection among IVDUs.

Methods

Subjects

IVDUs recruited between February 1988 and August 1989 for an AIDS education and intervention research program were paid a nominal fee to participate in an initial assessment interview, an education

TABLE 1—Needle and Drug-Related Behavior, Pretest/Posttest Comparisons Two Months Prior to Interview†

	n	Pretest	Posttest	Difference (95% CI)
Needle Behavior				
Scale means				
Using others' works	317	2.28	1.61	43.1 (36.0, 50.2)
Cleaning with bleach	315	1.86	1.87	—
% Sharing works	304	67.4	24.3	43.1 (36.0, 50.2)
% Using others' works	317	92.2	67.1	25.1 (19.4, 30.8)
% Sharing cooker	305	70.3	20.3	50.0 (44.5, 55.5)
% Using drugs IV	322	92.2	70.5	21.7 (16.1, 27.3)
% Cleaning with bleach	278	33.5	62.2	28.7 (21.0, 36.4)
Drug Behavior				
Means				
Number of drugs used	322	4.53	3.30	1.23 (1.13, 1.33)
Number of drugs used IV	322	2.24	1.43	0.81 (0.70, 0.92)
Heroin IV scale	278	4.24	3.32	0.92 (0.77, 1.07)
Cocaine IV scale	311	4.43	3.67	0.76 (0.63, 0.89)
Heroin use scale	322	3.49	2.15	1.34 (1.16, 1.52)
Cocaine use scale	322	4.47	3.27	1.20 (1.04, 1.36)
Speedball use scale	322	1.91	1.06	0.84 (0.70, 0.98)
% using heroin	322	65.5	45.7	25.9 (18.4, 33.4)
% using heroin IV	278	74.5	50.3	24.2 (16.4, 32.0)
% using cocaine	322	83.9	67.2	16.7 (10.8, 22.6)
% using cocaine IV	311	80.4	60.5	19.9 (13.8, 26.0)
% using speedball	322	40.7	27.3	13.4 (6.2, 20.6)

†The sample n varies from 322 due to missing values.

and intervention session, and a follow-up assessment begun at three months after the intervention. Pretest and posttest data were obtained on 402 subjects (60.7 percent of IVDUs from whom pretest assessments were obtained). Approximately 90 percent of the 402 subjects were street addicts not currently in treatment, and the remainder were new admissions to methadone treatment centers. The sample was predominantly male, predominantly Black, and had a median age of 36 years. Eighty subjects are not included in the analyses presented here because they were not considered to be at risk of HIV infection during the time between intervention and posttest (typically because of extended hospitalization, enrollment at a residential drug treatment facility, or incarceration) or because they participated in an alternative intervention. Most subjects were reinterviewed between three and five months after the intervention. However, because some subjects were hard to locate, the amount of time between intervention and posttest interview ranged from 36 to 448 days.

Risk Factor Measures

Pretest and posttest interviews employed multiple measures of two risk factors for HIV infection pertinent to IVDUs. Measures of risk related to needle behavior included sharing works, sharing a cooker, using drugs intravenously, using others' works, cleaning used works with bleach (each recorded as a dichotomy indicating whether the respondent had ever engaged in the behavior), and two scales measuring the frequency of using others' works and cleaning used works with bleach (where 1 = never, 2 = rarely, 3 = 25 percent of the time, 4 = 50 percent of the time, 5 = 75 percent of the time, and 6 = always). Measures of risk associated with more general issues of drug use included: number of drugs used, number of drugs used intravenously, scale scores of heroin use, cocaine use, and speedball use (where the scale is 0 = never, 1 = one to three times a year, 2 = monthly, 3 = one to three times a month, 4 = weekly, 5 = two to three times a week, 6 = four to six times a week, 7 = daily, 8 = two to three times a day, and 9 = four or more times daily), frequency of intravenous use of heroin, intravenous use of cocaine, and intravenous use of speedball (each recorded as the percent of the time that the drug is taken *intravenously* using the percentage scale described above). In addition, each of the variables pertaining to frequency of use or level of intravenous use was recorded as a dichotomy (never/at least once). All questions in the interview regarding these risk behaviors made reference to the two months immediately prior to assessment.

Intervention

The purpose of the quasi-experimental design (pretest-treatment-posttest) was to evaluate the impact of the educational intervention program. This intervention, presented in a one-on-one format by a professionally trained health educator, typically lasted from 45 minutes to an hour and was composed of four modules. The first module presented basic information about the HIV, common modes of transmission, and the progression of the disease. Because the seropositivity rate among IVDUs in Cleveland is quite low (estimates range from 3 to 6 percent based on several studies of selected groups of intravenous drug users conducted in Cleveland by the Cuyahoga County Drug Abuse Services Board) and consequently few of our clients had any immediate acquaintance with AIDS, this module centered on a segment from the film "AIDS: A Bad Way to Die,"*** produced by prisoners who were dying of AIDS. The second and third modules focused on reducing risks associated with sexual behavior and drug behavior. Condom use was demonstrated, and the relative risks of various sexual practices were discussed. Subjects were advised to modify their drug behavior by halting their use of drugs, not using drugs intravenously, not sharing works, or (as a defense of last resort against HIV infection) cleaning works when sharing with others and were shown how to clean a needle and syringe with bleach. Each subject was provided with a kit of materials including a bottle of bleach, condoms, and various brochures about AIDS. In the final module, subjects were told about the HIV antibody test and what both positive and negative results meant and were encouraged to take advantage of the anonymous blood testing provided as part of the project.

Evaluation of the intervention focused on three research questions:

- Do comparisons of pretest and posttest scores of risk behaviors provide evidence that the intervention was successful in reducing the level of risk for HIV infection among the respondents?
- In the absence of a true control group, can the impact of the intervention be assessed using a non-equivalent comparison group?
- Did the intervention have a sustained effect?

% Using cocaine-IV	55.6	70.1	50.5	9.16
% Using speedball	21.3	31.8	29.0	—

Results

Six of the seven needle behavior risk behaviors decreased in frequency at the posttest (Table 1). A major reduction was obtained in the percentage who reported sharing their works, and a considerable increase was obtained in the percentage who reported cleaning works with bleach. All 12 measures of risk associated with general drug behavior recorded significant risk reduction. No significant differences in risk reduction were found between IVDUs newly enrolled in treatment and those not in treatment, or between gender or ethnic groups. Additional analyses revealed no systematic variation among groups of IVDUs in terms of knowledge about AIDS at the time of pretest.

Comparison of Experimental and Control Groups

Since a true control group was ethically unacceptable, a non-equivalent control group was constructed composed of individuals who were interviewed for the pretest at approximately the same time as those interviewed for the posttest. For 19 of the 21 measures of risk associated with needle behavior, the "experimental" (posttest) group reported significantly lower levels of risk than the "control" (contemporaneous pretest) group. Similar contrasts were found in reduction of risk associated with general drug behaviors. (Details of these comparisons are available from the authors.)

Duration of the Impact

The important question of whether the intervention had a lasting impact on reducing high-risk behavior is difficult to answer directly since interviews were conducted at only two points in time for each subject. Fortuitously, indirect evidence can be obtained using the variation in the length of time between the intervention and the posttest interview. Subjects were divided into three equal-sized groups: those interviewed within 111 days of the intervention, those interviewed between 112 and 154 days following the intervention, and those interviewed more than 154 days after intervention. Comparisons of these groups in terms of the magnitude of risk reduction are presented in Table 2. While the results do not clearly establish the stability of the intervention's impact, neither do they suggest a significant decay over time. As in the previous analyses, a greater impact was observed for needle-related behaviors than for general drug use behaviors.

Discussion

The data demonstrate that significant changes occurred between pretest and posttest in needle and drug-related behaviors of intravenous drug users, and comparisons of experimental groups with contemporaneous non-equivalent control groups suggest that these changes are at least partly attributable to the intervention. In addition, the data indicate that the impact of the intervention endured for up to one year. Finally, while reductions were detected in a broad range of behaviors associated with a high risk for HIV infection, analyses suggest that the intervention had a greater impact upon specific needle-related behaviors (such as sharing works or cleaning works) than upon more general drug-related behaviors (such as frequency of heroin or cocaine use.) All of these effects were achieved across gender and ethnic groups. These data replicate many of the findings of other earlier panel studies.[3,4,7]

Several specific limitations of the study should be noted:

- Measures of risk are based exclusively on self-report. A number of studies indicate that addicts in research projects are usually honest respondents,[8–10] and interviewers were trained to elicit the subjects' confidence. The hour-long interview was fairly complicated making misrepresentations difficult to maintain. Moreover, the variability in findings in this report (and the generally less favorable impact of the intervention upon sexual behavior to be reported elsewhere) convinces us that our data are generally reliable.
- The use of convenience sampling complicated by self-selection bias and attrition weakens generalizations to a population. Although it does not completely dispel concerns about sample bias, a comparison of dropouts and those subjects who completed the study revealed almost no significant differences in terms of pretest risk behaviors, gender, ethnicity, or age. (These data are available from the authors.) This suggests that the final study sample adequately reflects the original sample of all subjects at pre-test.
- The lack of a true control group lessens the extent to which issues of internal validity can be adequately addressed.[11]

Despite these shortcomings, these findings suggest that many addicts act in a rational fashion when faced with important choices regarding behaviors which are directly AIDS-related. It appears that the educational intervention was successful because it sensitized the subjects to the realities of AIDS, established AIDS as a real threat to them, and then immediately armed them with knowledge and materials (bleach, condoms, and assorted literature) to assist them in their own risk-reduction efforts. Levels of drug use seem somewhat resistant to intervention in this sample. However, when faced with the prospect of disease and death from AIDS, many addicts seemed willing to modify their behavior—particularly the ways in which needles and related paraphernalia are used—in order to minimize the chance of infection. ☐

Acknowledgments

This research was sponsored by a grant from the National Institute on Drug Abuse (RO1-DA05151). The authors would like to thank Brian Gibbs for his assistance in conducting the statistical analyses. The authors also wish to express appreciation to William C. Bailey, PhD, Richard Bingham, PhD, and William Morgan, PhD, for their helpful comments on an earlier draft of this paper.

Harbor-UCLA Selected for Psychiatry Research Center

The National Institute of Mental Health (NIMH) recently approved the establishment of the nation's first mental health research center, the Research Center of the Psychobiology of Ethnicity, at the Harbor-UCLA Medical Center in Torrance, California. The $1.5 million grant will be administered by Harbor-UCLA's Research and Education Institute.

Alan I. Leshner, PhD, Acting Director of NIMH, said, "Although mental illness can strike anyone regardless of race or cultural origin, there appear to be some very important differences in the ways people of different ethnic backgrounds respond to medications in the treatment of depression, schizophrenia and other serious mental disorders. The research undertaken by the Harbor-UCLA Hospital Center will greatly enrich our understanding of the psychobiological bases of mental disorders and their treatment, and help ensure that every patient of every ethnic background receives appropriate treatment."

Center director Keh-Ming Lin, associate professor of psychiatry at Harbor-UCLA, described the focus of the center's programs as multidimensional and designed to serve the multiethnic populations of the community. The center will study the role that race and ethnicity play in the differing responses to treatments of serious mental illnesses. Drugs used in the management of mental depression, mania, and schizophrenia have been shown to have differing impacts, and to reach different levels in the blood and the brain, with ethnicity being a significant variable.

In addition to the study of biological issues and their impact on mental illnesses in people of differing ethnicity, the center will also study how cultural factors influence the evaluation and care of patients, and how they impact on the willingness of patients and families to make use of treatments and support programs found useful in mental health care.

Lin explained that "a very serious problem exists among minority patients and their families because they rarely make use of the self-help and patient/family support groups like the California Alliance for the Mentally Ill which provide so much assistance to those who do participate."

Lin and his colleagues are currently involved in a research project with Hispanic patients and families to identify ways to make treatment programs and self-help group activities more culturally acceptable and to increase access for these individuals to such programs. Other studies underway focus on the effect of mental illnesses on Asian, Black, and Native American patients and their families.

Adult Survivors of Childhood Sexual Abuse and Subsequent Risk of HIV Infection

Sally Zierler, DrPH, Lisa Feingold, MSPH, Deborah Laufer, MSPH, Priscilla Velentgas, Ira Kantrowitz-Gordon, ScB, and Kenneth Mayer, MD

ABSTRACT

Background: Epidemiologic description of long-term adverse health effects of childhood sexual abuse is lacking, despite estimates that perhaps 30 percent of adults have experienced sexual assault in childhood.

Methods: In an adult cohort enrolled to investigate causes of transmission of human immunodeficiency virus, we identified current behaviors affecting risk of infection that were associated with a history of early sexual abuse. One hundred and eighty-six individuals provided information on the occurrence of abuse and subsequent sexual and drug using activities.

Results: Approximately half of the women and one-fifth of the men reported a history of rape during childhood or adulthood. Twenty-eight percent of the women and 15 percent of the men recalled that they had been sexually assaulted during childhood. People who reported childhood rape compared with people who did not were four times more likely to be working as prostitutes (90 percent confidence interval = 2.0, 8.0). Women were nearly three times more likely to become pregnant before the age of 18 (90% CI = 1.6, 4.1). Men who reported a history of sexual abuse had a twofold increase in prevalence of HIV infection relative to unabused men (90% CI = 1.0, 3.9).

Conclusions: The disturbing prevalence of early sexual abuse and its possible health-related consequences call for prompt and routine investigation of sexual abuse histories. Identification of sexual victimization may be an important component for management of risk factors for human immunodeficiency virus. (*Am J Public Health* 1991;81:572–575)

Introduction

The social sciences have become increasingly concerned with the prevalence and psychosocial consequences of sexual abuse in childhood.[1-10] Prevalence studies in communities of free-living adults estimate that 6 to 62 percent of women and 3 to 31 percent of men were sexually abused before the age of 18.[11] The range in these estimates is a function of the specificity of the definition of sexual abuse and the age definition for childhood. When the definition is limited to children under 14 years of age who reported physical contact of a sexual nature, estimates range from 28 to 36 percent.[3] In 1985, the American Humane Association reported 123,000 cases of childhood sexual abuse during that year alone, and yet this figure is likely to be a gross underestimate.[11]

Childhood sexual abuse is a medical problem that requires careful diagnosis and follow up for trauma,[12] pregnancy,[13] disease transmission, including human immunodeficiency virus (HIV) infection,[13-16] and acute psychological morbidity.[11-13,17,18] Two behavioral outcomes that are associated with sexual abuse in childhood are chemical substance abuse and prostitution.[10,11] These risk-taking behaviors have health-related consequences that theoretically could include any diseases resulting from intravenous drug use or unprotected sexual activity with multiple partners. Infection from HIV would be associated with childhood sexual abuse if such abuse predisposes children to drug using or sexual behaviors that involve contact with bodily fluids infected with this virus.

An explicit goal of our study of determinants of heterosexual transmission of HIV infection in the Rhode Island area was to learn if a history of sexual abuse is a risk factor for subsequent HIV infection in adulthood. We hypothesize that adults who were sexually abused as children are more likely to participate in activities that increase their risk of exposure to HIV.

Methods

Study Population

All women and men at least 18 years old, residing or attending school in southeastern New England, currently or recently sexually active with someone of the opposite sex, and who signed an informed consent statement to participate in the research protocol were eligible to be in the study. Potential study volunteers contacted the study clinic as a result of the recommendation from a health care provider (provider-referred) or because of interest stimulated by a large scale publicity campaign (self-referred).

From the population of 567 women and men who enrolled in the testing and counseling program between March 1988 and October 1989, 393 people were invited to participate in the longitudinal study because they had a nonzero risk of acquiring or transmitting HIV infection (either because they had multiple sexual partners, were themselves HIV-infected, or had

*22 individuals reporting first abuse as adults were deleted from all subsequent analyses.

partners who were infected or at increased risk for HIV infection). Selection of the cohort and the decision to participate were independent of a history of childhood sexual abuse, since a history of sexual abuse was not known by the study personnel at the time of enrollment, nor had the potential participant seen or completed the questionnaire which investigated that history. There were 206 people who were eligible for the longitudinal study but refused to participate. The discontinued study population relative to the continuing study population was more likely to be male and less likely to be HIV-infected. The people who discontinued compared with those who agreed to remain were similar with respect to their age distribution, number of different sexual partners, race and ever use of intravenous drugs. Among the 187 individuals who agreed to continue in the study by signing a second informed consent statement, 186 had complete information on history of sexual assault. This population provided the information for the current study.

Exposure Information: A certified HIV counselor or nurse-clinician administered a lengthy behavioral questionnaire to study participants at the time they agreed to be in the longitudinal study. Information on the exposure of interest, a reported history of sexual abuse, was based on the question, "Have you ever been raped or forced to have sex?" People who acknowledged a history of sexual abuse further remarked on the frequency and timing of this occurrence (during childhood, adolescence, adulthood or during any combination of these time periods).

For the purpose of this analysis, individuals were defined as exposed to childhood sexual abuse if they reported a history of rape or forced sex at least once during childhood or as a teenager. Individuals were defined as not exposed if they reported no history of rape or forced sex, including during adulthood. Individuals reporting a history of first rape as an adult (n = 22) were excluded from the analyses due to our inability to determine a temporal sequence between exposure to sexual abuse and the outcomes of interest.

Outcome Information: Outcomes of interest included behaviors that may increase risk of acquiring HIV infection, as well as biologic parameters such as a history of sexually transmitted disease or current HIV infection. Information for the behavioral outcomes was obtained from the questionnaire administered at entry into the longitudinal study. Individuals provided information on their lifetime use of intravenous and non-intravenous illicit drugs, alcoholic beverages, contraceptives, and prior or current work as a prostitute. Detailed history of number of sexual partners, number of casual sexual partners, number of years of sexual activity, sexual practices, education, and pregnancy experience provided additional information on relevant outcomes.

Sexually transmitted disease history was obtained by self-report. HIV antibody status was determined by serologic testing by standard enzyme-linked immunoassay and Western Blot procedures using fresh blood samples that were drawn at the time of entry into the study.

All outcome measurements were created as dichotomous variables defined as the presence or absence of the outcome of interest. Examination of non-intravenous drug use and alcohol use was limited to those reporting no history of intravenous drug use because of the strong association of intravenous drug use with nonparenteral use of other drugs.

Data Analysis: Prevalence ratios provided a quantitative measure of risk between the outcome of interest and child sexual abuse. Prevalence ratios were computed as the proportion of people who had a particular outcome within the population who reported a history of child sexual abuse relative to the proportion who had this outcome within the population who reported no history of sexual abuse at any time.

Multiple logistic regression was used to examine the possible confounding effects of gender, race, and study referral source. Evaluation of confounding indicated that race and referral pattern did not materially change the coefficient for the child abuse term (for all outcomes, the coefficient for child abuse changed less than 5 percent) and therefore these potential confounders were deleted from the analysis. Table 1 lists the demographic characteristics of the cohort that was included in the analysis.

Because gender was the only measured confounder, and also because of in-

*22 women and 39 men intravenous drug users deleted from analysis.

**Prev ratio$_{MH}$ are Mantel-Haenszel estimates pooled over gender strata.

†Drug use was defined as ever use of these drugs (no use was defined as never used); Heavy alcohol use was defined as usual consumption of at least one bottle of wine, five cans of beer, or one pint of hard liquor when drinking (no heavy use was typically drinking less than this amount.)

terest in describing gender-specific associations, all analyses were stratified by gender and summarized as Mantel-Haenszel summary prevalence ratios with 90 percent test-based confidence intervals.[19]

Results

Approximately one out of every two women and one out of every five men reported a history of rape or forced sex (Table 2). The proportion of women and men who reported sexual abuse during childhood or adolescence was 28 and 15 percent, respectively.

The associations for behavioral characteristics and exposure to early sexual abuse appear in Table 3. Survivors of child sexual abuse were four times more likely to report having worked as a prostitute during their lifetime than were those who reported no history of abuse. This higher prevalence of prostitution among survivors was seen among both women and men. Male survivors of abuse were nearly eight times more likely to report a history of prostitution. All of the men reporting prostitution also reported bisexual experiences. Excluding male prostitutes, bisexuality among men was not associated with childhood sexual abuse (prevalence ratio = 1.1). Additional analyses, simultaneously controlling for gender and intravenous drug use, a behavior that may lead to prostitution as a source of income for drugs, resulted in only a slight lowering of the point estimate (prevalence ratio = 3.6, 90 percent CI = 1.8, 7.3). Use of intravenous drugs was only weakly associated with a history of early sexual abuse.

Penetrative sex without a condom with a partner suspected of having HIV infection was similar among survivors of child sexual abuse and among those not abused (prevalence ratio = 1.1). No difference between the two groups existed with respect to the lack of condom use in the year prior to enrolling in the study. Survivors of sexual abuse, however, reported a 40 percent excess frequency of a history of sex with someone they did not know, and were two times more likely to have multiple sexual partners on an average yearly basis relative to people reporting no sexual abuse.

Women who survived sexual abuse had greater than a three-fold increase in risk of not completing high school than women who reported no sexual abuse. This increase was explained in part by a higher occurrence of teenage pregnancy among the women who did not finish high school. Adjustment for pregnancy prior to the age of 18 lowered the point estimate for the relation between education level and sexual abuse history from 3.4 to 1.9 (90 percent CI = 0.8, 4.3). Teenage pregnancy was more prevalent among female survivors of sexual abuse than among those reporting no history of abuse (prevalence ratio = 2.6, 90 percent CI = 1.6, 4.1).

Table 4 describes drug use associations among people with no history of intravenous drug use. Survivors of sexual abuse had a 70 and 80 percent excess of use of tranquilizers and heavy alcohol use, respectively, relative to people reporting no sexual abuse. Women were two times more likely to be heavy consumers of alcohol if they had experienced sexual abuse in childhood than women who did not report this experience.

Overall, survivors of child sexual abuse were only slightly more likely to report a history of sexually transmitted disease (gender-adjusted prevalence ratio = 1.3, 90 percent CI = 0.93, 1.9) or to have serologic evidence of HIV infection (gender-adjusted prevalence ratio = 1.3, 90 percent CI = 0.82, 2.0). However, men who reported early sexual abuse had a two-fold increase in prevalence of HIV infection relative to unabused men (90 percent CI = 1.0, 3.9). This increased prevalence of HIV infection among men who survived sexual assault was not explained by a history of intravenous drug use.

Discussion

National estimates are that one in four girls and one in six boys are sexually assaulted before the age of 18.[20] Over one-fifth of our cohort acknowledged that they had been raped or forced to have sex during childhood or adolescence. This experience was twice as frequent among women as among men.

We do not have evidence of confounding of sexual abuse effects. Our observations are consistent with other studies that have described sexual abuse to be independent of race.[4,11] Unidentified correlates of childhood sexual abuse that are independent risk factors for behaviors leading to HIV infection could explain the positive results in this study. However, we did not ask about child and adolescent experiences other than those related to sexual and reproductive experiences and age of first use of illicit drugs. Childhood sexual abuse, particularly if the perpetrator is a family member, may be accompanied by other forms of abuse and neglect.[9] Our study did not investigate characteristics of family dysfunction that may be associated with both sexual abuse and adult behaviors leading to HIV infection.

We have evidence that early sexual abuse is associated with behavioral outcomes that may be having devastating effects on the public health, particularly in relation to the HIV epidemic. In our study, sexually abused women and men were more likely to engage in sex work, to change sexual partners frequently, and to engage in sexual activities with casual acquaintances than people who were never sexually abused. Women survivors of sexual assault reported more frequent use of large quantities of alcoholic beverages and both genders used tranquilizers more frequently than individuals who had never been assaulted.

The disturbing prevalence of early sexual abuse and its possible consequences on increasing behaviors that could lead to HIV infection and other poor health outcomes have implications for medical and public health practitioners. The safer sex messages, for example, may be missing the point for people whose lives have been complicated by sexual victimization. Social scientists have urged for early identification of children and adolescents who may have been sexually assaulted because of evidence that the earlier the child can begin recovery from this trauma, the better the prognosis for normal adult functioning[3,18] The high frequency of occurrence of sexual assault is not only an immediate threat to the health of children, but may continue to disrupt development of appropriate health behaviors that prevent disease in adulthood. □

Preventing Homicide: An Evaluation of the Efficacy of a Detroit Gun Ordinance

Patrick W. O'Carroll, MD, MPH, Colin Loftin, PhD, John B. Waller, Jr., DrPH, David McDowall, PhD, Allen Bukoff, PhD, Richard O. Scott, James A. Mercy, PhD, and Brian Wiersema

ABSTRACT

Background: In November 1986, a Detroit, Michigan city ordinance requiring mandatory jail sentences for illegally carrying a firearm in public was passed to preserve "the public peace, health, safety, and welfare of the people."

Methods: We conducted a set of interrupted time-series analyses to evaluate the impact of the law on the incidence of homicides, hypothesizing that the ordinance, by its nature, would affect only firearm homicides and homicides committed outside (e.g., on the street).

Results: The incidence of homicide in general increased after the law was passed, but the increases in nonfirearm homicides and homicides committed inside (e.g., in a home) were either statistically significant or approached statistical significance (p = .006 and p = .070, respectively), whereas changes in the incidence of firearm homicides and homicides committed outside were not statistically significant (p = .238 and p = .418, respectively). We also determined that the ordinance was essentially unenforced, apparently because of a critical shortage of jail space.

Conclusions: Our findings are consistent with a model in which the ordinance had a dampening effect on firearm homicides occurring in public in Detroit. The apparent preventive effect evident in the time series analyses may have been due to publicity about the ordinance, whereas the small nature of the effect may have been due to the lack of enforcement. (*Am J Public Health* 1991;81:576–581)

Introduction

The homicide rate in Detroit, Michigan, was the highest among the 15 largest United States cities in all but three of the last 15 years.[1,2] In 1986, the crude homicide rate in Detroit was 59 per 100,000, the highest of any large city in the United States. As is the case nationally, most homicide victims in Detroit were killed with firearms. In 1985 in Michigan, firearm homicides accounted for 72.7 percent of the homicide-attributable premature loss of life among Blacks. Two-thirds of Michigan's homicides occurred in the Detroit area.[3]

On November 26, 1986, the Detroit City Council, responding to a wave of youth homicides, enacted an ordinance[4] that imposed a mandatory jail sentence on anyone convicted of unlawfully concealing a pistol or carrying a firearm in the city. Although the ordinance contained some technical amendments to the city ordinances regulating the carrying and selling of firearms, the key element of the ordinance was the mandatory sentence of 30 to 90 days in the Wayne County jail and a fine of $100 to $500, depending on whether or not it was a first conviction under the ordinance. The ordinance became effective on January 10, 1987.

One of the primary goals of this legislation was to improve the health of the citizens of Detroit by decreasing firearm-related injuries and deaths. It was specifically stated in the ordinance that this legislation was "necessary for the preservation of the public peace, health, safety, and welfare of the people of the City of Detroit." This ordinance may therefore be viewed as a public health intervention, and its efficacy evaluated in that context.

Underlying this ordinance is the hypothesis that, by decreasing the number of persons carrying firearms on the streets of Detroit, the incidence of firearm homicides resulting from interpersonal violence occurring "outside" (e.g., on streets, in alleys, or in parking lots) would likewise decrease. Since the ordinance does not address the issues of possessing or keeping firearms in private places (such as the home) or of carrying other weapons (such as knives) in public, the law should have its greatest effect on the incidence of firearm homicides and homicides committed in public places while having little effect on the incidence of nonfirearm homicides or on firearm homicides committed inside private residences and other buildings.

To determine whether the imposition of the mandatory jail sentences in January 1987 was associated with changes in the incidence both of homicides committed with firearms and homicides committed outside, we analyzed homicide incidence data in the City of Detroit for the years

1980 through 1987. For comparison, we also analyzed nonfirearm homicides and homicides committed inside residences and other buildings. We predicted that changes attributable to the 1987 ordinance would be reflected in the incidence of firearm homicides and homicides committed outside, but not in the incidence of nonfirearm homicides or homicides committed inside.

In addition, we evaluated the enforcement of the mandatory sentencing ordinance by the criminal justice systems in Detroit. Although one might assume that the ordinance would increase the average sentence for persons convicted of illegally carrying a firearm in Detroit, experience in Detroit and other locations indicates that mandatory sentences do not necessarily produce the expected changes in average sentences.[5-9] For a variety of reasons, judges find ways to circumvent the mandatory sentences, or discretion for sentencing moves to another point in the criminal justice system such as the prosecutor or the police. An examination of how the law was implemented is therefore essential to the interpretation of the time-series analysis. In addition, the Detroit experience is important for what it may reveal about how a criminal justice system adapts to mandatory sentencing for carrying a firearm illegally.

Methods

Evaluating Effect of the Ordinance

Homicide data for the years 1980 to 1987 were drawn from computerized Official Complaint Report (OCR) records maintained by the Detroit City Police Department. All criminal homicides were included in the analysis, including offenses coded as murder, murder (1st degree), murder (2nd degree), and manslaughter.

OCR codes were used to divide the homicides two ways: 1) those in which the victim was killed with a *firearm* (handgun; shotgun/rifle) or by *some other means* (bodily force; black jack; knife, dirk, razor/other sharp objects; blunt object; miscellaneous other); and 2) those in which the victim was killed *outside* (on street; off street, alley; playground/park; parking lot; in a vehicle; vacant lot) or *inside* (building; housing project). Four cases in which the homicide method was coded as "missing" and 73 cases coded as "unknown" were assigned to the nonfirearm series on the grounds that firearm homicides are easily recognized. The police data did not permit a determination of whether homicides in "buildings" occurred in private buildings (such as in a home) or in public buildings (such as in a bar or convenience store). Including homicides in public buildings in our *outside* series would have been preferable, since weapons used to commit such homicides would presumably have been carried "outside" to these buildings, and thus the perpetrators should theoretically have been affected by the ordinance. Nevertheless, if a substantial proportion of the homicides in buildings occurred in public buildings, this would result in a bias toward the null in our study since it would tend to dampen the hypothesized preventive effect on homicides committed outside relative to those committed inside.

Inferences about the impact of the ordinance on homicides are based on an interrupted time-series research design that contrasts the monthly incidence of certain types of homicide before and after the ordinance took effect. A change in the behavior of a particular time series at the point of intervention would provide evidence that the ordinance had an effect on that time series. To measure the size and statistical significance of time-series changes associated with the implementation of the gun ordinance, we used the intervention analysis developed by Box and Tiao based on the Box and Jenkins autoregressive, integrated, moving average (ARIMA) modeling of time series.[10,11] In general terms, the procedure starts with the development of a *noise model* to account for systematic components—trend or drift, seasonality, and autocorrelation in the time series. Modeling these systematic components to explicitly remove their effects is important because it reduces the risk that these components will be confounded with an intervention effect. This noise model essentially controls for variables which influence the homicide rates consistently over time, allowing analysts to estimate the effects of the intervention. After an appropriate noise model to control the effects of these series characteristics has been specified, an *intervention* model is added to represent the effect of the ordinance. If there is a change in the series at the point of intervention, the intervention model will measure the size of the effect.

Ideally, we would have conducted the analysis on monthly observations for each of the four time series resulting from the logical intersection of the two dimensions of interest: 1) firearm homicides in public places; 2) nonfirearm homicides in public places; 3) firearm homicides in nonpublic places; 4) nonfirearm homicides in nonpublic places. However, there were insufficient cases to permit ARIMA modeling of the time series in this manner. Therefore, we conducted two separate monthly analyses: one for firearm versus nonfirearm homicides (categories 1 + 3 versus 2 + 4) and one for public versus nonpublic homicides (categories 1 + 2 versus 3 + 4).

All estimates were computed using the backforecasting algorithm implemented in BMDP2T software.

Evaluation of Enforcement

To assess the impact of the mandatory jail sentencing ordinance on the processing of gun ordinance violators in the Detroit criminal justice system, we monitored the disposition of cases charged under the ordinance during 1987 and 1988 using data that are routinely collected by the prosecutor and the court. In addition, we conducted non-structured interviews with key people in the Detroit criminal justice system, people whose jobs involved implementing the ordinance or processing defendants charged with violating the ordinance, e.g. members of the Detroit Police Department, the Department of the Wayne County Prosecuting Attorney, the Office of the Detroit Corporate Council (city solicitor), the 36th District Court, and others. These interviews were not intended to constitute a scientific survey; rather, they were intended to supplement the statistical analysis of the disposition of offenders charged under the ordinance by allowing a description of perceptions regarding the enforcement of the ordinance by those most likely to be well informed in this regard.

Results

Findings of the Time-Series Analysis

The two sets of time series data—firearm vs nonfirearm homicides, and inside vs outside homicides—are plotted in Figures 1 and 2. The results of the interrupted time-series analyses of these data are summarized in Table 1. For each of the four series that we analyzed, the table shows the estimated size of the intervention effect (in terms of the change in the number of homicides per month associated with the intervention); the mean number of homicides per month before the intervention; the relative magnitude of the intervention effect (expressed as a percent change in the preintervention mean number of homicides per month); and the

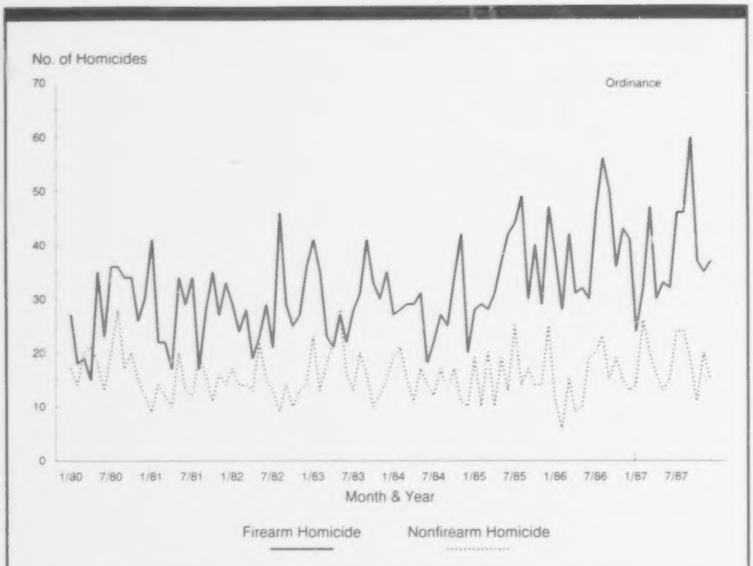

FIGURE 1—Number of Homicides in Detroit by Month and Weapon Used, 1980–87

p-value, representing the probability of a Type-I error associated with a test of the null hypothesis of a zero intervention effect. In the Appendix, we provide more complete information on the time-series analysis.

The clearest feature of the analysis, reflected in the positive estimates of the intervention effect in all four series (Table 1) is that in January 1987, as the ordinance was implemented, Detroit was experiencing a substantial increase in homicides. This is consistent with the public perception in Detroit of increasing homicide incidence. As noted above, this perception is what stimulated the Council to pass the mandatory sentencing ordinance.

Although the ordinance clearly failed to stop the surge, a comparison among the various time series of changes associated with the intervention in the mean number of homicides per month suggests that the ordinance may have had a dampening effect on the increasing incidence of homicide. Homicides committed inside (those unlikely to be affected by the ordinance) increased by 22 percent, a much greater increase than the 10 percent increase in homicides committed outside (those more likely to be affected by the ordinance). The statistical analysis shows that the increase in inside homicides is large relative to its standard error (see Appendix) and is therefore unlikely to be due to a chance fluctuation (p = .006); the increase in outside homicides, however, is small relative to its standard error and is compatible with a variation attributable to chance (p = .418). The data are therefore consistent with a model in which the incidence of homicides committed inside increased, but the incidence of homicides committed outside was unchanged.

A similar but less pronounced pattern exists for the firearm/nonfirearm contrast. The incidence of nonfirearm homicides increased 16 percent after the intervention, a change that is large relative to the standard error of the series and therefore relatively unlikely to be due to a chance fluctuation (p = .07). Although the incidence of firearm homicides increased almost as much (13 percent over the mean of the preintervention series), the change was small relative to its standard error and not statistically significant by conventional standards (p = .24). In other words, the increases in the two types of homicide most clearly targeted by the ordinance were not statistically significant; plausibly the increases observed were random fluctuations around the preintervention mean. In contrast, the increases in the two comparison series that were least likely to be influenced by the ordinance either were clearly statistically significant or approached statistical significance at the p = .05 level. The patterns are what would be expected if the Detroit gun ordinance had a dampening effect on firearm homicides and outside homicides.

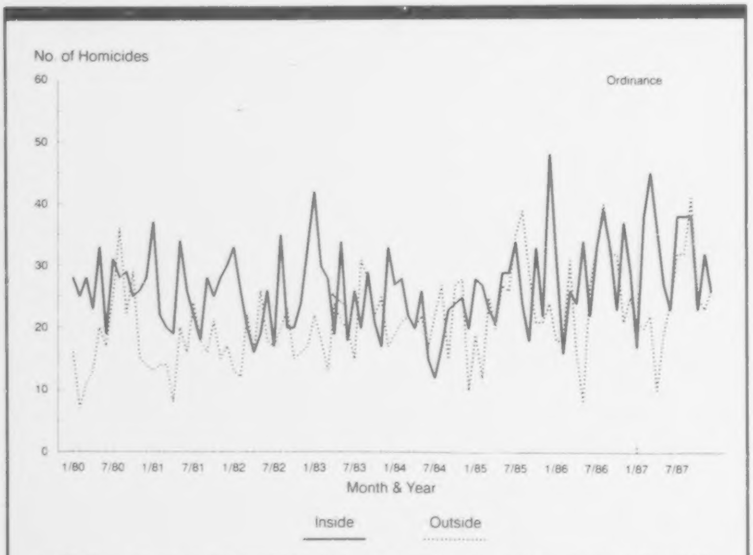

FIGURE 2—Number of Homicides in Detroit by Month and Location of Homicide, 1980–87

Enforcement of the Ordinance

The research design assumes that the ordinance resulted in the mandated change in jail sentences for illegally concealing a pistol or carrying a firearm. We determined, however, that the law did not result in any such change. The records of the 1,020 persons charged under the ordinance whose cases were processed as of early 1989: only 22 defendants (2.2 percent) were sentenced to jail and eight others (0.8 percent) were given credit for jail time served while waiting disposition of their case. These findings were confirmed informally through our interviews with key criminal justice personnel. Two years after the ordinance was passed, everyone we interviewed who was in a position to observe sentencing practices agreed that extremely few of those who were arrested for carrying concealed weapons ultimately received the mandatory sentences stipulated in the ordinance.

The administrative context in which the ordinance is enforced explains why it failed to increase the certainty or severity of sentences. Since long before the ordinance was passed, officials at the Wayne County Jail had been under court order to reduce overcrowding and improve living conditions. This order had transformed jail space into a scarce and expensive commodity. Judges had to choose who among the misdemeanants, ordinance violators, and pretrial felony defendants to incarcerate in the 1,676-bed county jail. Our informants agreed unanimously that it was impossible to enforce the mandatory sentencing provisions of the ordinance because not enough jail space was available. Given a choice between incarcerating violators of the gun ordinance versus pretrial felony defendants or other offenders who had committed more serious offenses such as violent assault or robbery, ways were found to avoid the mandatory sentencing provision of the gun ordinance.

TABLE 1—Summary of Interrupted Time-series Analysis of the Effect of a Gun Ordinance on the Incidence of Homicide, Detroit, Michigan, 1980 to 1987

Homicide Series	Estimate of Intervention Effect	Mean Number of Homicides[a]	Percentage Change in Series[b]	P-value for Test of H_0 = no change
Inside	5.798	25.95	22	.0058
Outside	2.086	20.83	10	.4179
Nonfirearm	2.524	15.56	16	.0703
Firearm	4.109	31.42	13	.2380

[a] The mean number of homicides per month in the preintervention series adjusted, where appropriate, for autocorrelation.

[b] The intervention effect as a percent of the mean of the preintervention series.

Discussion

Unquestionably, homicide is an enormous public health problem in the United States.[12] Viewed strictly from a health perspective, the numbers of deaths and injuries from assaultive violence have certainly reached epidemic proportions in some American cities. Public health authorities have rightly called for increased efforts to address this urgent health problem by whatever means are determined to be both effective and societally acceptable. The descriptive epidemiology of homicide is clear on three salient points: 1) many homicide victims are killed by friends or acquaintances; 2) many homicides occur as a result of an argument, frequently over relatively trivial matters; and 3) approximately six out of 10 homicides are committed with firearms, usually handguns.[13] On the basis of these observations, several investigators have hypothesized that many homicides could be prevented if ready access to firearms were reduced, since many violent altercations occurring among family, friends, and acquaintances would then necessarily be resolved by less deadly means.[14-16]

The Detroit gun ordinance evaluated here is one approach to decreasing the accessibility of firearms. Theoretically, by reducing the number of persons carrying firearms on the streets of Detroit, some violent public altercations that might have resulted in fatal gunshot injuries would result in other nonfatal outcomes. Our time-series findings are consistent with a model in which the ordinance had a relatively small preventive effect on the incidence of homicides in Detroit. More importantly, the effect is found precisely where we predicted we would find it, based on our hypothesis that the ordinance would affect the incidence of firearm homicides and homicides occurring outside but not the incidence of other types of homicide.

We also found that the Detroit ordinance requiring mandatory sentences was almost completely unenforced. If the ordinance was never enforced, how can any preventive effect, small or otherwise, be ascribed to it? During the period from November 1986 through January 1987, media coverage of the passage of the ordinance was extensive and public debate about the virtues of the ordinance was heated. In several articles, local officials pledged to enforce the law strictly and to provide jail space as necessary. This publicity may have been responsible for the preventive effect that we found associated with the promulgation of the ordinance. The lack of enforcement—and the coincident ending of the publicity surrounding the law's passage after January 1987—may account for the relatively small nature of the observed effect.

Little previous research has been done on the effectiveness of laws that require mandatory sentences for carrying firearms illegally. To date, the most extensive studies of this issue dealt with the Massachusetts Bartley-Fox Law which required a mandatory minimum one-year sentence for carrying a firearm illegally. Investigators reported that the Bartley-Fox law reduced the number of robberies, assaults, and homicides committed with a firearm.[5,17] A more in-depth study of assaults, however, revealed that, whereas assaults with firearms decreased, assaults without firearms increased. This raises the question of whether a reduction in firearm-carrying results in a displacement rather than a reduction in interpersonal violence. In the case of the Bartley-Fox law, the apparent increase in nonfirearm assaults appears to have been due to increased reporting of more minor assaults after the law was implemented.[17] From a public health perspective, however, this issue is moot: a displacement of interpersonal violence from altercations in which firearms are used to altercations in which firearms are not used would most likely have the desired effect of preventing many homicides.

In addition to the intuitive appeal of reducing homicides in public by reducing the public carrying of firearms, ordinances such as this one in Detroit are worthy of close evaluation for several other reasons. First, the law imposes relatively few costs on individual citizens who own and use firearms for purposes such as hunting or protection. The ordinance does not prevent a person from keeping a firearm in the home. In addition, under the ordinance a firearm may be legally transferred from place to place (e.g., from the home to a firing range or out to a hunting area) as long as it "is unloaded in both barrel and magazine and is taken down, enclosed in a case, carried in the luggage compartment of the vehicle or inaccessible from the interior of the vehicle." The ordinance only prohibits carrying a concealed, loaded pistol on one's person, or any

$\text{ARIMA}(1,0,0)(1,0,0)_{12}$ $a_t = (1 - \phi_1 B)(1 - \phi_{12} B^{12}) Y_t - \Theta_0$ $\hat{\Theta}_0 = 31.42$ s.e. = 1.54[illegible] $\hat{\phi}_1 = .2791$ s.e. = .1016 $\hat{\phi}_{12} = .2301$ s.e. = .1115 Box-Ljung Q = 19 with 23 degrees of freedom	$Y_t^* = a_t + \omega_0 (I_t)$ $I_t = 0$ for months 1–84 $I_t = 1$ for months 85–96 $\hat{\omega} = 4.109$ s.e. = 3.4885

loaded firearm in a car in such a manner that it could readily be retrieved.

Second, the notion that local governments have the right to determine who may legally carry loaded firearms in their jurisdictions appears to be relatively well accepted and not subject to much of the controversy surrounding "gun control." Indeed, the Detroit gun ordinance may be considered innovative only because of the inclusion of mandatory sentencing provisions. If such laws are generally considered to represent a reasonable function of local government, then—should scientific study demonstrate their utility in preventing homicide—ordinances like the one in Detroit might be adopted in other jurisdictions with relatively little controversy.

In contrast to the minor costs imposed by the ordinance on individual citizens, however, the general costs associated with arrest, adjudication, and mandatory incarceration of violators of the ordinance are *not* trivial. As noted in our evaluation of the enforcement of the Detroit ordinance, jail time is frequently both a scarce and expensive resource, and mandatory sentence laws, if enforced, would certainly increase the numbers of persons in jail, at least in the short term.

Given the dearth of similar research, the relatively small magnitude of the effect observed in Detroit, and the fact that the Detroit ordinance was not enforced, our findings must not be considered definitive. Reasonable caution requires that the study be replicated in a setting in which a similar ordinance is effectively and visibly enforced. Despite the theoretical and practical appeal of the Detroit gun ordinance, assessing the effectiveness of such ordinances in preventing homicide is imperative before public health officials advocate their wider adoption by other localities. In addition, the feasibility of proper, visible, and ongoing enforcement of such laws should also be assessed. Merely passing an ordinance to decrease the carrying of loaded firearms in public is clearly not adequate. Moreover, passing but not enforcing such ordinances may have unanticipated negative consequences. The inevitable ineffectiveness of an unenforced ordinance might lead policy makers to the inappropriate conclusion that such ordinances are *inherently* ineffective. If laws are passed to curtail the number of people carrying loaded firearms in public, they must be enforced. If such laws are passed *and* enforced, then the public health community should miss no opportunity to evaluate the effect of these laws on the rate of injury and death from firearms violence in public. □

Acknowledgments

We gratefully acknowledge William F. Hart, Chief of Police, Detroit Police Department; Adger Butler, PhD, Jack Samuels, PhD, and Jim Klein for their assistance in the conduct of this study. We would especially like to thank Michael Fried, Chief, Administration Division of the Wayne County Prosecutor's Office, who opened doors for us and provided many useful insights.

This paper was presented at the annual meeting of the American Society for Criminology in Reno, Nevada, November 10, 1989.

The statistical analysis presented herein was independently reviewed and confirmed by Daniel J. Schnell, PhD, Mathematical Statistician, Division of STD/HIV Prevention, Center for Prevention Services, Centers for Disease Control.

Fellowship Fund at UCLA to Benefit American Indian Students

The George Blue Spruce, Jr., Fellowship Fund for American Indian Students was recently established at the University of California at Los Angeles, School of Public Health. Named in recognition of George Blue Spruce, Jr., of Phoenix, Arizona, the fellowship will provide for scholarships and loans to American Indian students preparing for careers in the field of public health. The fellowship is administered by the Health Careers Opportunity Program at the school, under direction of a committee composed of American Indian alumni from the UCLA School of Public Health.

Dr. Blue Spruce, who comes from the San Juan/Laguna Pueblo Tribes of New Mexico, was the first American Indian to graduate as a dentist in the United States. His doctorate of dental surgery is from Creighton University. Blue Spruce's career in health service includes work as a US Navy dental officer, clinical assignments on Indian reservations, assistant surgeon general in the US Public Health Service, director of the Office of Native American Programs in the US Office of Human Development, and consultant in dental health for the World Health Organization, In addition, he has chaired the Intra-Departmental Council of Indian Affairs in Washington, DC and was director of the Phoenix Area Indian Health Services for the Department of Health Services.

To date, approximately 30 American Indians have completed advanced degree programs at the UCLA SPH. The George Blue Spruce, Jr., Fellowship Fund is the third fund established at the school to support the recruitment and retention of minority students. In 1987, the Richard Chavez Scholarship Fund was established for Hispanic students, and in 1990 the Betty Smith Williams Scholarship Fund was established for African-American students.

For further information and donations to the fellowship, contact: Health Careers Opportunity Program, UCLA School of Public Health, 41-240, Los Angeles, CA 90024-1772.

Cervical Papillomavirus Infection and Cervical Dysplasia in Hispanic, Native American, and Non-Hispanic White Women in New Mexico

ABSTRACT

Background: Human papillomavirus infections of the cervix are found with varying frequencies in different populations worldwide, and have been associated with cervical cytologic abnormalities.

Methods: We studied 1,603 randomly selected Hispanic, Native American, and non-Hispanic White women in New Mexico to determine the prevalence of cervical HPV infection in these ethnic groups, and its association with Pap smear abnormalities, using a new commercial dot-blot hybridization assay.

Results: Nine percent of all women screened had evidence of cervical HPV infection (13.7% of non-Hispanic White women, 9.7% of Hispanics, and 6.6% of Native American women). Prevalence was higher in younger women ages 14–19 years than in older age groups. Over half of women with cervical HPV infection (n = 145) had normal Pap smears. The proportion of infected women increased among those with more advanced cytopathologic abnormalities; 5.6 percent with normal Pap smears had cervical HPV vs 66.7 percent with moderate-severe dysplasia.

Conclusions: Cervical HPV infection is common among New Mexico clinic attendees, varies in prevalence among the three major ethnic groups, and is strongly associated with cervical cytopathologic abnormalities. (*Am J Public Health* 1991;81:582–586)

Thomas M. Becker, MD, Cosette M. Wheeler, PhD, Nancy S. McGough, RN, Scott W. Jordan, MD, Maxine Dorin, MD, and Jill Miller, MD

Introduction

Human papillomavirus (HPV) infections of the genital tract are among the most common sexually transmitted viral infections in the United States.[1-3] Recent estimates have suggested that as many as 12 million adults in this country may be infected with genital HPV.[3] In addition to causing genital warts, HPV infections may also result in clinically inapparent lesions of the cervix. Cervical HPV infection can be diagnosed by certain morphologic features on colposcopy,[4] by cytopathologic changes seen in Papanicolaou (Pap) smears,[5] through detection of HPV antigen by immunoperoxidase stains,[6] or by identification of HPV DNA sequences in hybridization studies.[7,8] Hybridization techniques, considered more sensitive and specific than most other types of HPV tests,[9] have shown the presence of HPV genomes in 6–30 percent of women tested for cervical abnormalities from various populations worldwide.[10-15] The use of recently developed polymerase chain reaction-based HPV diagnostic tests suggests that cervical HPV prevalence may be even higher than has been determined by hybridization methods.[16,17]

New Mexico's population is comprised primarily of three major ethnic groups—Hispanics, Native Americans, and non-Hispanic Whites. In prior reports, we have shown variation in the incidence and prevalence of many infectious and chronic diseases among these ethnic groups,[18-22] including invasive and pre-invasive cervical cancer.[23] As part of an ongoing cohort study to investigate the natural history of cervical HPV infection, we studied Hispanic and non-Hispanic White women attending the University of New Mexico (UNM) gynecology clinics, and Native American women attending local Indian Health Service (IHS) hospital clinics to determine ethnic differences in the prevalence of cervical HPV infection using a newly developed hybridization test, and the relationship of cervical HPV infection to cervical cytologic abnormalities in these ethnic populations.

Methods

Study Sample

Subjects were women who attended the UNM gynecology clinics and the Albuquerque IHS hospital-affiliated clinics, June 1988–September 1989. On randomly selected days of the week, providers screened all women on whom a pelvic examination was performed for any reason. This sampling scheme was consistent among clinics and sites and all five clinic days (Monday–Friday) were equally likely to be selected. Patients who underwent a pelvic examination for any reason were included in this survey. The UNM clinic attendees were comprised primarily of Hispanic and non-Hispanic White women; few women of other ethnic or racial groups attend these clinics. At the UNM clinics, Hispanic ethnicity is either

determined by self-identification at the time of clinic enrollment or is assigned by clinic staff on the basis of Spanish surname. To validate the UNM clinics' designation of Hispanic and non-Hispanic White ethnicity, we interviewed a 15 percent sample of the UNM clinic group studied. We found 91 percent concordance between the self-reporting of Hispanic or non-Hispanic White ethnicity compared to the combined self-identified/clinic staff assignment of ethnic status. The Indian Health Service hospital clinics serve primarily Pueblo and Navajo women. No attempt was made to validate Native American ethnicity. We did not include in our report those Black women who were screened at the UNM clinics for cervical HPV (n = 7). Informed consent was required at three of the four clinics affiliated with the UNM gynecology department. Only two refusals to participate in the screening survey were recorded among all clinic patients; both of these patients were of Hispanic ethnicity.

UNM clinics serve primarily women who are economically disadvantaged. The IHS-affiliated clinics provide services free of charge to eligible Native American patients. Nonetheless, Native Americans in New Mexico are an economically disadvantaged group: approximately 40 percent of the state's Native American population lived below the poverty level in 1980.[24]

Cytopathologic Diagnoses

Pap smears from the UNM clinics were all read by the same cytopathologist (SWJ); cytologic smears from the IHS hospital were initially read by pathologists from Path Labs, El Paso, Texas. We found 98 percent concordance between these two laboratories for diagnoses of a sample of normal cervical smears (n = 59). The UNM cytopathologist (SWJ) reviewed all abnormal Pap smears which were initially reported by Path Labs for the IHS clinic attendees. To maintain consistency in cytopathologic diagnoses for this report, we used the UNM cytopathologist's diagnoses for abnormal Pap smears in our analysis. Cytopathologic changes associated with HPV infection (such as koilocytosis) were coded as atypias for this report. All diagnoses corresponded to the World Health Organization's criteria for cervical cellular abnormalities.[25] During the period of this survey, the newly developed Bethesda Classification System for cervical cytology had not been implemented in either pathology laboratory.[26]

HPV Testing

We used a recently developed dot hybridization screening test, ViraPap® (Life Technologies, Inc, Gaithersburg, MD 20857) to test for cervical HPV infection. This test is designed to identify genital HPV types 6, 11, 16, 18, 31, 33, and 35—the types most commonly associated with genital tract infection. The test includes sampling the endo- and exocervix with a dacron-tipped plastic swab for exfoliated cells. HPV samples were collected after the Pap smears were collected. Dacron swabs were placed immediately in tubes of ViraPap™ collection media. The tubes were frozen at −20°C until testing in batch at the HPV laboratory, University of New Mexico School of Medicine. All positive HPV ViraPap tests underwent typing using the ViraType® test (Life Technologies, Gaithersburg, MD 20857). This dot hybridization test is able to separate HPV genome into the three categories, 6/11, 16/18, and 31/33/35, but does not determine which of the virus types is present within a given category. All borderline test results by ViraPap were further tested by ViraType and considered negative only if they were negative by the ViraType test.

The HPV laboratory independently validated the sensitivity and specificity of ViraPap and ViraType using Southern Blot hybridization techniques as the "gold standard".[16,17] For 147 specimens, the sensitivity of the ViraPap assay was 100 percent and specificity 96 percent. For 63 specimens, the sensitivity of the ViraType assay was 100 percent and specificity 91 percent.

Data Analysis

Data were analyzed using standard packages from SAS.[27] We examined the age-adjusted prevalence of cervical HPV infection for Hispanic, Native American, and non-Hispanic White women between the ages of 15 to 44 years using the combined population distribution for these study patients in this age range as our reference population. We age-adjusted these figures using the direct method of standardization.[28]

Results

We studied 535 Hispanic, 322 non-Hispanic White, and 746 Native American women, a total of 1,603 women. The mean ages of the participants were 25.0 years for the Hispanic women (range 15–43 years), 25.5 years for non-Hispanic Whites (range 14–50 years), and 29.5 years for Native American women (range 14–78 years). The prevalence of cervical HPV infection in this sample was higher for non-Hispanic White women (13.7 percent) than for Hispanic (9.7 percent), or Native American women (6.6 percent). The age-adjusted prevalence of cervical HPV infection was 13.1, 9.3, and 7.7 percent for non-Hispanic White, Hispanic, and Native American women, respectively, between the ages of 15 to 44 years. Among all women with cervical HPV infection, Native American women had a higher proportion of HPV 6/11 compared to non-Indian women (Table 1).

Younger women were more likely to have cervical HPV than were women in older age groups (Table 2). Comparable age-related decreases were observed in each of the three ethnic populations which we studied (data not shown). For all women combined, 6.7 percent of patients screened had slight, moderate, or severe dysplasia. American Indian women had a higher proportion of Pap smears showing atypias, compared to Hispanic and non-

Hispanic white women (Table 3). Table 4 shows that a large proportion of the 145 women with evidence of cervical HPV infection had normal Pap smears (55.9 percent), but that the prevalence of HPV increased sharply with the degree of dysplasia found in the Pap smear.

Discussion

Our data show ethnic differences in the prevalence of cervical HPV infection, as well as ethnic differences in types of HPV present on the cervix at the time of the screening examination, and substantiate prior published observations that HPV is more commonly found in more advanced cervical lesions.[3,12] Unlike most prior reports, however, our survey showed that HPV types 31, 33, and 35 were often present in association with cytologic abnormalities.

The prevalence of cervical HPV infection in different populations worldwide varies substantially, depending on the diagnostic test employed for HPV detection. Using cytologic criteria, Meisels and Morin[5] reported that 1.7 percent of 234,715 women who participated in a screening program in Quebec, Canada, between 1975–1979 had cytologic evidence of cervical HPV infection. In other cytologic surveys, prevalence estimates ranged from 0.9 percent to 16 percent.[1,29–33] Among these reported series, the prevalence has been higher in sexually transmitted disease clinics[29,32,33] than in other clinic populations. Research which has employed DNA hybridization techniques found evidence of cervical HPV DNA to vary from 6 to 28 percent of women tested,[10–15] with several studies reporting a prevalence of about 10 percent.[11–15,29,33] Using Southern blot hybridization for evidence of HPV 6, 11, 16, or 18 DNA, deVilliers, *et al*,[12] found the highest prevalence of HPV DNA was from cervical specimens from women less than 25 years of age (14 percent), and the lowest prevalence among women age 56 or older (4 percent). Similarly, Kiviat, *et al*, reported a higher prevalence of cervical HPV DNA in women 16–24 years old who attended a sexually transmitted disease clinic or a student health clinic in Seattle, Washington compared with older age groups of women at both clinics.[33]

HPV types 16, 18, and 31 have been implicated as having a more aggressive role in malignant transformation of cervical cells.[34–38] Our screening data cannot address the issue of malignant transformation; however, if published observations on the malignant potential of HPV 16, 18, and 31 are accurate,[11,36] many of the clinic attendees we studied in New Mexico are at high risk for development of cervical cancer. Nonetheless, current epidemiologic evidence is too weak to accurately assess the relationship of specific HPV types in genital cancer etiology: carefully designed prospective studies are necessary which consider other potential risk factors in the development of disease. Ethical considerations, however, cannot allow clinicians to follow patients to the end-point of cervical cancer without earlier intervention; thus, the appropriate studies to determine the relationship between HPV infection and cervical cancer will probably never be carried out. Population-based screening for HPV (by type), together with examination of cervical cancer specimens for type-specific HPV genome from cases which occur in those same populations, may shed additional light on the relationship of specific HPV types in cervical cancer.

Although several case-control studies and one cohort study have indicated that the presence of HPV in cervical tissue is a strong risk factor for cervical dysplasia

or cervical cancer,[2,10,12,14,38,39] data on genital cancer incidence in New Mexico's Hispanics, Native Americans, and non-Hispanic Whites when compared to our survey findings appear to provide evidence that conflicts with these studies. The highest cervical cancer rates in New Mexico occur among Native American and Hispanic women, with rates for non-Hispanic White women which are comparable to those rates for whites nationwide[23]—the exact opposite of our survey of HPV prevalence. Although such ecological correlations are weak and do not consider numerous confounding factors in the infection-disease relationship, they suggest that we examine the epidemiology of cervical disease as related to HPV infection and to other relevant behavioral, infectious, and dietary factors more closely.

Our study has limitations that must be addressed. The HPV laboratory test we used, while demonstrating high sensitivity and specificity compared to Southern Blot hybridization for certain HPV types, is unable to determine the presence of genital HPV types other than those included in the test kit. The New Mexico clinic populations may thus contain an even greater proportion of women infected with other genital HPV types which have been identified in other populations.[40–42] Furthermore, implementation of highly sensitive polymerase chain reaction-based HPV diagnostic testing in other populations suggests that cervical HPV prevalence is considerably higher than can be determined by using hybridization methods.[16,17] Thus, it is likely that cervical HPV prevalence in our clinic populations may be higher as assessed through polymerase chain reaction techniques than we report using the commercial dot-blot assay. In addition, we have examined single specimens for the presence of cervical HPV infection; serial sampling of the same patients may result in the determination of an even greater number of women with cervical HPV infection. Poor technique in the collection of Pap smears or HPV samples could also influence our results; however, all clinicians who collected these specimens were instructed in proper sample collection techniques. Despite these potential sources of bias in our study, we have demonstrated that cervical HPV infection is common among university-affiliated and Indian Health Service hospital-affiliated clinic attendees in New Mexico; prospective studies are ongoing to evaluate the relationship of cervical HPV infection to the development of dysplastic lesions in these populations. □

Acknowledgments

This research was supported by a contract from the Indian Health Service, Contract No. 249-88-0013. We wish to thank Drs. William Reeves, Joseph Icenogle, Kay Stone, and Carlos Lopez of the Centers for Disease Control for advice and assistance, and Dorothy Fordyce for secretarial assistance. We are grateful to the staff at the Women's Health Care Clinic and the Maternal and Infant Care clinics, and to the staff at the Albuquerque Indian Health Service Hospital for their help in specimen collection. In particular, Diane Sampson, Sandi Jensen, and Marianne Wheeler assisted with specimen collection. We also appreciate the advice of Drs. Andrew Kramer, Del Endres, Charles North, and Eric Henley. Lynne Fullerton and Corinne Peek assisted with data collection. Dr. Richard Juel of Path Labs, El Paso, Texas, kindly provided cytologic smears for review.

New Report from Bureau of Health Professions

The Health Resources and Services Administration's Bureau of Health Professions (BHPr) recently announced publication of the summary report of its *Workshop on Modeling and Forecasting for the 1990s* (DHHS Pub. No. HRS-P-OD-90-5). This invitational workshop was sponsored by BHPr's Office of Data Analysis and Management. It focused on the desirability of utilizing a common framework of economic and health sector assumptions for all Bureau modeling and forecasting efforts.

The report summarizes the formal presentations and structured discussions of the more than 50 health services researchers from federal and state government, universities, and private research firms at the January 1990 workshop. Appendices include the workshop keynote address, agenda, schematics of BHPr models, selected references, and participant feedback.

Single copies of the report may be obtained by writing the Office of Data Analysis and Management, Howard V. Stambler, Director, BHPr, Rm. 8-47 Parklawn Bldg., 5600 Fishers Lane, Rockville, MD 20857; (301) 443-6936.

Urolithiasis in Tennessee: An Occupational Window into a Regional Problem

ABSTRACT

Background: Urinary tract stones (stones) are believed to be unusually common in the southeastern United States but neither the incidence of nor the risk factors for stones are known.

Methods: In three well-defined occupational populations in eastern Tennessee, we assessed the prevalence, incidence, and cumulative incidence of stones and measured biochemical risk factors for lithogenesis.

Results: The age-adjusted prevalence of stones was 18.5 percent in Tennessee compared to 7.7 percent among White males in US NHANES (prevalence ratio 2.4, 95% CI 1.7, 3.3). The cumulative incidence (risk) was 27.8 percent by age 65, higher than in any other reported population. Risk factors were age, a family history, and urinary saturation with calcium-oxalate (COAX). Persons with a positive family history and the highest measured CAOX index had a predicted lifetime risk of 88.8 percent. Biochemical factors affecting lithogenesis were hypercalcuria, hyperoxaluria, and low urine volume.

Conclusion: Future research should characterize the geographic boundaries of a southeastern "stone-belt" and explore genetic and dietary hypotheses that might explain it. (*Am J Public Health* 1991;81:587–591)

Michael J. Thun, MD, MS, and Susan Schober, PhD

Introduction

Kidney stones, an important source of morbidity, suffering, and medical expense, have received little epidemiologic attention. Three studies suggest an endemic area of stones in the Southeastern United States, but these rely upon hospital discharge data rather than incidence.[1–3] The absence of population-based incidence data in the US and the paucity of etiologic studies impede the identification of potentially modifiable risk factors such as diet and climate.[4,5]

The present study began as an investigation of reported urinary tract disorders among uranium workers in eastern Tennessee. Although no occupational association was found,[6] the study provided an opportunity to assess stone occurrence and risk factors for lithogenesis in a high-risk population. Our data support the concept of a regional "stone belt" and suggest clues as to its etiology.

Methods

Subjects

The uranium plant processed depleted and natural uranium and thorium from 1957 to 1970, and enriched uranium after 1970. Workers eligible for the study represent a gradient of exposure to unenriched uranium, compounds for which nephrotoxicity rather than radiation limits exposure.[7–9] The target population included: 1) highly exposed active, retired, and disabled production workers with 20 years employment before 1986; 2) a low exposure group of senior office and laboratory workers; 3) minimally exposed guards, ages 40–65, employed recently at the uranium plant; and 4) unexposed dairy workers from a nearby town. The dairy workers belong to the same trade union and local community. They produce tinned evaporated milk but have no special access to discounted milk or cheese that might affect stone risk.

Initially, a pilot questionnaire was administered to senior uranium workers and to guards. Later, a more extensive questionnaire and medical study were offered to the entire target population. Both questionnaires asked identical core questions about age and stones:

- "Have you ever had a kidney stone, including gravel in your urine?"
- "How many times have you had this?"
- "When did you first have this?"
- "Where were you treated?"

Workers interviewed in person were asked to sign a medical release form. The medical questionnaire also asked about a family history of stones, treatment for urinary tract infections, length of residence in the area, diabetes, hypertension, urinary instrumentation, prostatic disease, analgesics, smoking, "moonshine," and occupational exposure to heavy metals and solvents.

Data Collection

This activity included height, weight, seated blood pressure, serum for total calcium, phosphorus, uric acid and creatinine, sterile urine for quantitative urine culture and microscopy, and urine samples for chemistry, beta-2-microglobulin,

Total	210	208 (99)	123 (62)

*Participation in medical study based upon the number (199 total) of workers present locally when testing performed.

retinol binding protein, and enzymes.[6] Urine was collected over 24 hours to measure the "stone risk profile," including eight promoters of lithogenesis (calcium, oxalate, sodium, uric acid, sulfate, phosphorus, and high or low pH), and three inhibitors (citrate, magnesium, and urine volume).[10,11] During collection, participants maintained their usual diet, fluid intake, and activity. Urine pH was measured immediately upon return of the sample; volume was determined by dilution of a known quantity of lithium. Aliquots were shipped in dry ice for analysis.[6]

Supersaturation with CAOX, dicalcium phosphate, monosodium urate, and urate was computed from measured values using a computer algorithm that considers the complex physiochemical interaction between multiple factors.[12] Supersaturation scores are expressed relative to the group mean of 176 persons without stones.[12]

Statistical Analyses

Age-specific prevalence reflects the number of workers ever having had a stone divided by the number in the corresponding age bracket, based upon age at interview. Age-adjusted prevalence was compared to White males in NHANES II[13] using maximum likelihood estimation.[14] Age-adjusted incidence reflects the age at first stone. Person years at risk (PYAR) were computed using life-table methods. Workers contribute PYAR from birth until they develop a stone or complete the interview, whichever is first. Age-adjusted incidence in Tennessee was compared to published data from the Mayo clinic,[5] using maximum likelihood estimation;[14] 95% confidence intervals used the test-based method.[14] Cumulative incidence (based on age at first stone) used the Kaplan-Meier method.[15] Factors associated with stones were identified using Student's t-test (for continuous variables) and Chi-square (for proportions). Associations were further tested using unconditional logistic regression. In this analysis, cases are persons ever reporting stones. Terms considered in the regression are age and all factors in Table 4 associated with stones at $p < 0.2$. The effect of each risk factor was assessed separately and in the presence of others. Age is retained in the final model because of the known association of stones and age. Other factors are retained if statistically significant ($p < 0.05$) or if inclusion of the factor substantially influences the coefficient for other terms. Second degree interaction was tested using stratified analyses; interaction terms are not included in the logistic model because none of these substantially modify the main effect terms.

Results

Table 1 shows participation rates by employment category. Overall, 208 eligible workers (99 percent) completed the core questionnaire. Of 199 present locally during the medical testing, 136 (68 percent) completed the medical questionnaire and 123 (62 percent) provided blood and 24-hour urine samples (full medical study). Participation was highest among active hourly workers released from duty for testing. Guards, retired, and salaried workers were either off-site, not released from duty, or had lower commitment to the study. All participants were male, 206 were White, with an average age of 52.1 and range of 38–72 years.

Medical Record Review

Forty of 208 workers reported stones (crude prevalence 19.2 percent). Of these, 37 were treated by civilian physicians, 30 (all those interviewed in person) provided medical release forms, 28 received records from the treating facility, and 25 had a stone confirmed. Stones could not be confirmed when the treating physician had retired or relocated. Confirmed stones accounted for 34 hospitalizations, 42 abdominal X-rays, five surgical extractions, and five lithotripsies. Chemical analyses of stones were recorded on 13 persons with recurrent stones; calcium oxalate was present in 12 (92 percent). Nineteen persons reported multiple stones; five of these had from five to 20, and one had 32.

Prevalence

Table 2 presents the prevalence of stones by age and occupational group. At all ages, the Tennessee workers reported more frequent stones than did White males in NHANES.[13] The age-adjusted prevalence in the Tennessee workers was 18.5 percent vs 7.7 percent in NHANES (prevalence ratio 2.4, 95% CI = 1.7, 3.3). Stone prevalence was similar in all occupational groups except guards. Prevalence in guards was 7 percent, significantly lower than that of other workers ($p = 0.02$) and similar to NHANES.[13]

Incidence and Cumulative Incidence

The age-adjusted incidence of first stones was 4.21 per 1,000 person-years, compared to 1.03 per 1,000 in Minnesota males[5] (RR = 4.1, 95% CI = 2.9, 6.0). The cumulative incidence (risk) of stone by age 60 was 23.7 percent, and by age 65 was 27.8 percent.

Characteristics Associated with Stones

Table 3 shows selected demographic and clinical attributes of persons with and without stones. Stone-formers in our study weighed more, used moonshine liquor less, reported a more frequent family history of stones and of male relatives treated for urinary infections, and were more likely to be treated for such infections themselves. Laboratory findings associated with stones are a significantly higher serum and urine calcium, and urinary supersaturation with CAOX and brushite. Findings not associated with stones in our study but of interest in the literature are serum and urine uric acid,[16] current cigarette smoking,* and analgesic use.[17]

Table 4 presents the results of unconditional logistic regression. The two factors most strongly associated with stones were the index for CAOX supersaturation in a current urine sample, and a family history of stones. The logistic model (Table 4) categorizes the CAOX index into tertiles. In Figure 1, the CAOX index is presented as a continuous variable. Figure 1 illustrates the probability of stones, as predicted by the model, in persons with and without a family history over the range of the CAOX observed in our study. Males with a family history and the highest measured CAOX index have a predicted lifetime probability of stones of 88.8 percent. Using multiple linear regression, we determined that the most important determinants of the CAOX were high urinary calcium and oxalate and low urine volume. Together, these terms explained 91.8 percent of the variance, with the individual contribution of calcium, urine volume, and oxalate being 49.5 percent, 34.1 percent, and 8.2 percent, respectively. Six other stone risk factors used to compute the CAOX index were statistically significant at the $p < 0.001$ level, but together these added only 6.7 percent to the explained variance.

TABLE 2—Age-Specific Prevalence of Stones: Tennessee Workers vs US

	Number (Percent) with Stones			
	Tennessee (N = 208)		US NHANES[18] (N = 4331)

Total		208	40	(19)

Discussion

Our principal finding is an increased risk of stones among males in eastern Tennessee, consistent with previous reports of a regional "stone belt."[1-3] At highest risk are persons with a positive family history whose urine is supersaturated with CAOX, a major ingredient of most stones.[4] Provided that our findings reflect regional occurrence, they suggest that stones are an important public health problem in the southeast, and provide some clues about etiology.

The lifetime risk of stones among the Tennessee workers is higher than in any other reported population. Risk by age 60 is 24 percent in our study, compared to 5 percent in Minnesota,[5] 7 percent in northern California,[4] and [illegible] percent in Uppsala, Sweden.[18] These regional differences are larger than can be explained by differences in the methods for estimating risk. The Swedish data, for example,[18] are based upon a prevalence survey of renal colic in 1781 men, age 60. The US NHANES survey,[13] using similar methods but inquiring about stones instead of renal colic, show a lifetime prevalence of 9.2 percent in White males ages 60–69. The lower risks observed in the California and Minnesota studies are based upon incidence rates of physician visits.[4,5] Incidence is converted to risk using the formula [$\text{risk} = 1 - e^{(-\text{Incidence} \times \text{Time})}$].

Several findings suggest that the risk of stones in our study is regional rather than occupational. First, a family history of stones affecting first degree relatives who have never worked at either plant was common in both stone-formers (52 percent) and those without stones (21.5 percent). This can be compared to Sweden, where 29.4 percent of stone-formers and 15.3 percent of nonstone-formers report a family history.[18] Second, the occurrence of stones in the uranium workers bears no relation to the intensity or duration of occupational exposure. Stones are slightly less common in workers with direct exposure to uranium and thorium than in unexposed workers. Third, stone occurrence is similar in the uranium and dairy workers. If stone occurrence were due to occupation it would be unlikely that two such different occupational settings would cause a nearly identical effect.

The geographic boundaries of the so-called "stone-belt" are poorly defined. Four southeastern states (North Carolina, South Carolina, Virginia, and Tennessee) rank high in terms of hospitalizations for stones as a proportion of all hospital admissions.[1] There are limitations to these hospital discharge data, however,[4,5] and no studies have collected population-based data on incidence in the southeast US. Such data would be extremely useful in mapping the occurrence of stones, defining high-risk areas, and identifying preventable risk factors.

No cause has yet been identified for increased stone-formation in the southeast. Various hypotheses include water softness,[19] sunlight and heat,[20] dietary consumption of meat,[16] and carbonated beverages.[21] All of these hypotheses are based upon ecological evidence and have not been tested in studies assessing both stone occurrence and the exposure of individuals to the proposed risk factors. Our study is the first to measure biochemical risk factors in urine in a high-risk population; as such it helps to narrow the range of hypotheses to be pursued in future research. The single most important factor contributing to CAOX supersaturation in our study was increased urinary calcium.

Twenty-five (20.7 percent) of participants in the medical study had clinical hypercalciuria (>300 mg per 24 hours).[16] We did not obtain a dietary history and cannot assess whether the increased uri-

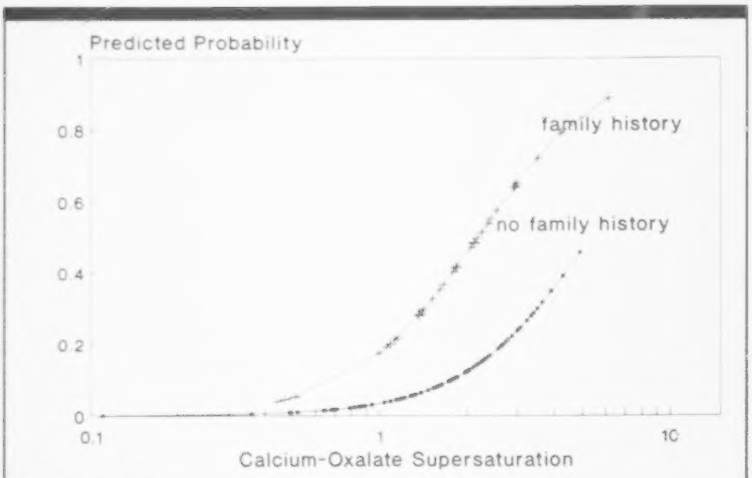
nary calcium was due to diet (milk, cheese, and meat) or to increased gastrointestinal absorption. However, we can exclude drinking water as a major source of calcium because municipal water supplies in the area have been monitored since 1982 and have unusually soft water due to low calcium.[22] Similarly, sunlight and its effect upon vitamin D cannot explain the measured values in our study, because the study was conducted in January. A second important determinant of CAOX was low urine volume. This cannot be attributed to incomplete urine collection, because it occurred in the presence of high 24-hour excretion of other stone risk factors. Low fluid intake is the most likely explanation for reduced urine volume and increased concentration. It is unclear why fluid intake should be low in these workers, although prohibition against alcoholic beverages in many areas of the southeast may play some role. Alcohol exerts a diuretic effect by suppressing the release of anti-diuretic hormone.[23] Consumption of moonshine liquor is negatively associated with stones in our study. The hypothesis that alcohol may protect against stones is plausible and deserves further evaluation.

Mildly elevated urinary oxalate (55–100 mg/24 hours)[24] occurred in 20 (16.5 percent) of the workers in our study. These levels are below those found in primary hyperoxaluria,[24] but may be consistent with dietary exposure. Foods commonly eaten in the southeast include several sources of oxalate (collards, mustard greens, kale, and ice tea).[25] Oxalate excretion contributed relatively little to urinary saturation with CAOX compared to hypercalcuria and low urine volume. However, the presence of oxalates in typical southern cuisine provides an intriguing hypothesis to be tested in future studies.

We cannot explain the low frequency of stones among the guards in our study. Guards were culturally different from the other workers. Twenty guards (46.5 percent) vs 10 (7.9 percent) of the other workers were retired military servicemen who had spent 20 or more years away from the area ($p < .0001$). Too few guards participated in the medical study to allow us to examine whether differences existed in their urine composition. The low participation occurred largely because guards



* defined in text

FIGURE 1—Probability of Stones by Family History and Calcium-Oxalate Supersaturation Index*

could not be released from duty to participate during working hours.

A limitation of our study is that the assessment of risk factors for stone-formation in urine is based upon a single 24-hour sample, obtained some years after the actual passing of stones. It is likely that excretion of most of these substances varies over time. Nevertheless, the strong association between current CAOX excretion and lifetime stone occurrence is consistent with the known importance of calcium and oxalate in stone formation. Excretion appears to be sufficiently stable to reflect a gradient of risk as current concentration increases. In summary, the study found an increased risk of urolithiasis and risk factors related to stone formation in male workers in eastern Tennessee. Future research should define the geographic range of increased kidney stone formation in the southeast and identify its causes. ☐

Acknowledgments

The authors thank the management, union, and workers of the three companies for their support. We thank Drs. Leslie Stayner and Victoria Wells for their help in the field testing, Brenda Lewis for laboratory assistance, Drs. Gary Diamond, Robert Goyer, Paul Morrow, and Richard Platt for peer review, Drs. Stacey FitzSimmons, Dana Flanders, and Charles Pak for their invaluable review of the manuscript, and Steven McGuire PhD and Judith Foulke, PhD, for serving as liaison project officers within the Nuclear Regulatory Commission (NRC). Support for the field and laboratory testing was provided by the NRC.

Benzodiazepine Anti-anxiety Agents: Prevalence and Correlates of Use in a Southern Community

Marvin Swartz, MD, Richard Landerman, PhD, Linda K. George, PhD, Mary Lou Melville, MD, Dan Blazer, MD, PhD, and Karen Smith, PhD

ABSTRACT

Background: Benzodiazepine anti-anxiety agents are the most widely prescibed psychotherapeutic drugs in the United States today. Recent evidence, however, suggests that their use may be decreasing.

Methods: We examine the population prevalence and correlates of use of benzodiazepine anxiolytics at the Duke site of the NIMH-sponsored Epidemiologic Catchment Area project.

Results: Bivariate analysis of use patterns for the drugs revealed demographic predictors similar to those reported in previous studies: increased likelihood of use by the elderly, Whites, women, the less educated, and the separated or divorced. Use is also associated with symptoms of psychic distress, negative life events, use of health care services, and diagnoses of affective disorder, agoraphobia with panic, and panic disorder. Age, sex, race, education, and marital status remain associated with non-hypnotic benzodiazepine use in a logistic regression analysis.

Conclusions: Multivariate analyses of these data indicate that when potential confounding factors are controlled, age, sex, race, education, and marital status are significantly related to benzodiazepine anxiolytic use but the effects of sex and education are mediated by intervening variables. Implications of these findings are discussed particularly in relation to high levels of use in the elderly. (*Am J Public Health* 1991;81:592-596)

Introduction

Benzodiazepine anti-anxiety agents are the most widely prescribed psychotherapeutic drugs in the United States today.[1] First introduced in 1960, these drugs rapidly achieved a lead position in the prescription drug market,[2] stimulating public and professional debate over appropriate psychotropic drug use.[3] Recent evidence, however, suggests that the prevalence and patterns of psychotropic use, especially those of benzodiazepine anxiolytics, may be changing and resulting in decreased use.[4,5] The first detailed population survey of psychotropic drug use, the National Household Sample in 1970–71,[6-9] found that 22 percent of American adults had used prescription psychotropic medication during the year 1969–70, with higher use among women and the elderly. The most commonly used drug group, "minor tranquilizer/daytime sedatives," was used by 8 percent of men and 20 percent of women. Use was greater in Whites and in divorced, separated, and widowed persons and the elderly.[6] In 1979, the National Survey of Psychotherapeutic Drug Use documented, using weighted data, that an estimated total of 8 percent of men and 13.7 percent of women had used benzodiazepine anxiolytics in the previous year with the greatest use among respondents ages 50–64.[2,10] Recent surveys of the St. Louis area population[11] and Great Britain[12] found lower overall rates of use but similar sex and age usage profiles.

Previous studies have relied primarily on bivariate analyses when describing patterns of drug use, failing to take into account the intercorrelations among predictors, including demographic, diagnostic, symptoms, and service use variables. In the present study we examine the prevalence and patterns of benzodiazepine antianxiolytic drug use in the Piedmont region of North Carolina during 1982–83, utilizing logistic regression analysis, which allows prediction of benzodiazepine use while introducing controls for potential confounding and mediating variables.

Method

The present paper reports results from Wave 1 of the Piedmont Health Survey, one site of the five-site National Institute of Mental Health Epidemiologic Catchment Area program (NIMH-ECA).[13] The sampling frame for the Piedmont Health Survey (PHS) was a five-county area in north central North Carolina, consisting of one urban county and four contiguous rural counties. The survey randomly sampled all housing units from segments throughout the catchment area, using the Kish method,[14] yielding 3,798 interviews usable for this study; further details of the study have been published elsewhere.[15] In this paper analyses are based on weighted data, taking into account household probability selection, nonresponse, and the 1980 census demographic profile of adults in the five-county catchment area. For significance tests, the data were downweighted to the original number of subjects, but weighting adjustments remain.

Diagnoses were obtained through use of the Diagnostic Interview Schedule

Address reprint requests to Marvin Swartz, MD, Box 3173, Duke University Medical Center, Durham, NC 27710. This paper, submitted to the Journal March 12, 1990, was revised and accepted for publication December 12, 1990.

(DIS), a highly structured interview designed for use by lay interviewers in epidemiological studies and capable of generating computer-based diagnoses for certain DSM-III disorders.[16] The diagnoses generated by the DIS were too numerous to include in a single regression equation. Preliminary analyses ascertained that an affective disorders summary measure (consisting of major depressive disorders, bipolar disorders, dysthymia, and bereavement), panic disorder, and agoraphobia with panic were most strongly related to benzodiazepine use. These measures were retained for subsequent analyses. The version of the DIS used in Wave 1 of this survey and other ECA sites did not include one anxiety disorders diagnosis, generalized anxiety disorder, employed at certain ECA sites in follow-up interviews.

In the present study psychotropic drug use refers to any use within the year prior to interview, regardless of amount or duration of use and was elicited by specific drug use probes aided by photographic drug identification cards. Other measures used for this analysis include a 29-item psychic distress scale analogous to the SCL-90,[17] and the number of negative life events during the year prior to the interview, measured by a scale of 20 major events of the type proposed by Holmes and Rahe.[18] Analyses of life events in the survey have been published elsewhere.[19,20] Interviewers also recorded the number of outpatient visits to physical and mental health providers during the six months prior to interview. The measure of outpatient health service utilization employed in this study is dichotomous, because the use vs non-use measure has more explanatory power than a continuous (number of visits) measure. Demographic variables used in this report include sex, age, race, education level, marital status, and urban vs rural residence. Income is excluded because preliminary analyses indicated that the relationship between anxiolytic use and income is weak.

The Appendix presents a six-stage causal model predicting the dichotomous measure of use vs nonuse of benzodiazepine anti-anxiety agents. A unidirectional causal process is assumed with variables in prior stages affecting those in subsequent stages. No causal direction is assumed for variables in the same stage. In the multivariate logistic regression analysis below, effects of the stage I variables are estimated first, and the equation is then expanded as groups of variables are entered by stage. This format yields an estimate of the effect of each variable net of all adjacent and prior variables and indicates whether the effects of prior variables are mediated by subsequent variables. The logistic regression procedure calculates maximum likelihood estimates for the parameters of a model that express the log odds of an event (here, drug use) as a simple linear model.[21,22]

Results

Table 1 presents the demographic profile for subjects participating in the survey.Table 2 focuses specifically on use of benzodiazepine anti-anxiety agents—predominantly diazepam and chlordiazepoxide—regardless of source. All other anxiolytics as well as all sedatives and hypnotics (benzodiazepine and other) are excluded. Table 2 presents a cross-tabular analysis of the weighted prevalence of benzodiazepine anxiolytic use among various demographic and other groups of interest. For two continuous variables, correlation coefficients are used: the correlation coefficient of drug use with number of negative life events is .09 ($p < .01$) and that for drug use with psychic distress symptoms is .20 ($p < .01$). Benzodiazepine anxiolytic use is more prevalent among women, older persons, Whites, and those with less education. The never married and married have significantly lower prevalence of use than the divorced and widowed. Respondents who have recently used either physical or mental health care services are much more likely to use these agents, as are those with a DIS diagnosis of affective disorder, panic disorder, or agoraphobia with panic.

Table 3 presents results of the logistic regression analyses. The "OR" coefficient in the table is the antilogged regression coefficient and estimates how changes in the independent variables multiply the odds of using benzodiazepine anxiolytics, holding other variables in the equation constant. Ninety-five percent confidence intervals are also given. The overall fit of the model is assessed by R statistic which is roughly analogous to the multiple correlation coefficient in ordinary least squares regression after correcting for the number of parameters estimated.[22]

[a] The total of some cells do not equal 3,798 because of missing data.

[b] The percents may not sum to 100 due to rounding.

[c] The weighted percentage adjusts the actual response percentage to take into account household probability selection, response rate, the elderly oversample and demographic characteristics of the 196,790 persons in the five-county area who were 18+ years of age. (Total five-county population, based on 1980 census data, was 269,863.)

[d] Other races are almost entirely Black.

In stage I, older persons and women are both more likely than others to use benzodiazepines, while Blacks are less likely. The gender effect decreases substantially in stages V and VI indicating that much of the initial sex difference is due to higher levels of psychic distress and health service utilization among women. The race effect changes very little across stages indicating no substantial effect of potential mediating variables. While the coefficients for age fluctuate across stages, they remain largely unmediated and substantial at stage VI. In stage II, increases across each of four levels of education (as indicated in Table 2) reduce the odds of benzodiazepine use by .9. This initial effect decreases in stages IV and V, indicating that those with more education use benzodiazepines less, in part, because they have fewer DIS diagnoses and psychic distress symptoms. Compared to the never married, the separated, divorced, and widowed are more likely to use benzodiazepine anxiolytics. These marital status effects are not mediated by varia-

[a] Significant at the .05 level or better. Where a particular set has more than two categories, significance test applies to the set.

bles entered in subsequent stages. Urban residence is not strongly associated with drug use. In stage III the number of negative life events is positively and substantially associated with drug use. Decreases in this effect in stages IV through VI indicate that the effect of negative life events is due primarily to the effects of life stress on DIS diagnoses, psychic distress symptoms, and increased health care utilization. In stages IV through VI, affective disorder, agoraphobia with panic, and panic disorder are all associated with increased benzodiazepine use, as are psychic distress and health care utilization. However as can be seen in the final model, effects of DIS diagnoses are mediated by psychic distress.

Discussion

Multivariate analysis of survey data indicates that when potential confounding factors are controlled, age, sex, race, education, and marital status are related to benzodiazepine anxiolytic use. Age, race, and marital status remain substantially unmediated by other factors while sex and education, previously thought to be predictors of anxiolytic use, exert their effects indirectly via their relationships with other predictors in subsequent model stages. The effect of education is mediated by intervening factors such as high levels of psychic distress or stressful life events. Women indeed use more anxiolytics, but probably because they either have or report more distress than men and/or are more likely to seek help. That is, net of the effect of increased levels of psychic distress and help-seeking among women, women are no more likely than men to receive and/or use anxiolytics, indicating less evidence for sex bias in prescribing practices and use than suggested in previous studies and the press.[11,23–25]

One of the most important findings in the present study relates to increased anxiolytic use in the elderly, many of whom are already medicated and/or cognitively impaired.[2] Benzodiazepine use in the elderly is a particular concern because the use of long half-life benzodiazepines such as the ones included in the present study is associated with an increased risk of hip fracture,[26] creating a potentially fatal complication of anxiolytic use in this population. High levels of use in the elderly raises concerns about the judicious use of these agents.

The differential rates of anxiolytic use by race, lower among Blacks even when predictors such as use of health services are controlled, cannot be explained further in the present analysis. These results do suggest possible racial bias in prescribing practices and/or different modes of help-seeking and alleviation of psychic distress among Whites vs Blacks. Prior studies have demonstrated that separated or divorced respondents have higher levels of life stress and psychic distress[9] and are more likely to use anxiolytics, presumably as a result of these stressors.[6,9] Our analyses suggest, however, that separated and divorced persons have a greater likelihood of drug use even net of negative life events and psychic distress, suggesting other explanatory or predispositional factors, not examined in the present analysis.

Finally these analyses raise questions about associations between symptoms, diagnosis, and appropriate psychotherapeutic drug use. There is evidence that the American public has become more conservative in its attitudes toward psychotropic drug use.[2,27] In fact, our preliminary data indicate that the majority of persons with high levels of anxiety in the community are not receiving psychotherapeutic medications; further analyses need to ex-

plore whether they are receiving other psychotherapeutic interventions. There is also a strong association between a DIS diagnosis of affective disorder and use of benzodiazepine anxiolytics. Concurrent use of antidepressants is not examined in the present study. However, Craig, *et al*, also found that surveyed women taking minor tranquilizers and sedatives included significantly more respondents with high depression scores, and that depressed respondents of both sexes tended to be taking anxiolytics or sedatives, and not antidepressants.[28] Beardsley, *et al*,[29] found that primary care practitioners provided 72 percent of all anxiolytic drug visits, but documented a psychiatric diagnosis in a minority of anxiolytic drug visits, raising questions about the specificity of anxiolytic use in primary care settings. Although anxious and depressive symptoms are often admixed, the present findings of high anxiolytic use among depressed respondents suggest that depressive symptoms are underrecognized. Major depressive episodes usually require specific antidepressant medication and psychotherapy, and treatment with benzodiazepine anxiolytics in the absence of more specific antidepressant therapy may postpone therapeutic response or even exacerbate symptoms.[23,30,31]

We have examined the current prevalence of benzodiazepine anxiolytic use in a Southern community, demonstrating that age, sex, race, education, and marital status are significantly associated with drug use, but that the effects of sex and education are mediated by intervening variables. In addition we have found benzodiazepine anxiolytic use to be significantly associated with several DIS diagnoses although the effects of diagnoses are largely mediated by psychic distress and use of health services. Future research on this population will focus on duration and frequency of anxiolytic use, use of other psychotropic drugs, and use of potentially interacting drug combinations. Finally, more detailed DIS diagnostic information gathered at follow-up of the survey cohort, including generalized anxiety disorder, will allow closer examination of the associations between benzodiazepine anxiolytic use and DIS diagnoses of affective and anxiety disorders. ☐

The Influence of Three Mass Media Campaigns on Variables Related to Adolescent Cigarette Smoking: Results of a Field Experiment

Karl E. Bauman, PhD, John LaPrelle, PhD, Jane D. Brown, PhD, Gary G. Koch, PhD, and Connie A. Padgett, BA

ABSTRACT

Background: This paper reports findings from a field experiment that evaluated mass media campaigns designed to prevent cigarette smoking by adolescents.

Methods: The campaigns featured radio and television messages on expected consequences of smoking and a component to stimulate personal encouragement of peers not to smoke. Six Standard Metropolitan Statistical Areas in the Southeast United States received campaigns and four served as controls. Adolescents and mothers provided pretest and posttest data in their homes.

Results and Conclusions: The radio campaign had a modest influence on the expected consequences of smoking and friend approval of smoking, the more expensive campaigns involving television were not more effective than those with radio alone, the peer-involvement component was not effective, and any potential smoking effects could not be detected. (*Am J Public Health* 1991; 81:597-604)

Introduction

There is general agreement that cigarette smoking is the major preventable cause of death in the United States and that efforts to prevent smoking onset should be directed toward young people.[1]

Few studies have evaluated the influence of broadcast media on adolescent smoking.[2] Lewitt, Coate, and Grossman concluded that youth smoking rates were reduced by messages broadcast on radio and television.[3] The awareness of negative personal and social consequences of smoking increased among Minnesota adolescents after the introduction of campaigns that involved television, radio, and billboards.[4] Worden, *et al.*, found fewer reports of friend smoking, but no less smoking, among adolescents in a rural Vermont county that received a television campaign than in four matched control counties.* Flay, *et al.*, found no effects on smoking intention or behavior by a coordinated television and school-based prevention program.[5] Research on mass media campaign effects for behaviors other than smoking rarely involves adolescents (see, for example, Rice and Atkin[6]).

The purpose of this research was to evaluate the impact of mass media campaigns intended to prevent adolescent cigarette smoking.

Methods

The Mass Media Campaigns

The three mass media campaigns evaluated in this research are described in detail elsewhere.[7,8] They were developed with the guidance of behavioral science theory and research, one year of extensive formative research, and the principle that they could be implemented readily throughout the United States.

One campaign used eight 30-second radio messages that focused on seven expected consequences of smoking that are related to whether young people become regular smokers. We identify this campaign, and the areas in which it was implemented, as RADIO.

The second campaign (RPEER) was similar but also included a 60-second radio message that invited persons 12 to 15 years old to enter the "I Won't Smoke Sweepstakes." The purpose of the sweepstakes was to obtain names and addresses. We mailed entrants a brochure that asked them to talk to their friends about not smoking, to encourage their friends to pledge not to smoke, and to have their friends enter the sweepstakes. We offered a $20 incentive for recruiting five or more

entrants. The brochure also was mailed to friends they recruited.

The third campaign (RTVPEER) was similar to the second but included television broadcast of the sweepstakes offer and only three of the expected consequences messages.

The expected consequences messages were broadcast throughout November 1985, January 1986, and April 1986. The sweepstakes offer was broadcast during November 1985 and the brochures to encourage personal peer contact were mailed from January 1986 through February 1987. To simulate implementation of a national campaign, an advertising agency purchased broadcast time. The agency placed the messages at times expected to reach 75 percent of the intended audience four times during each of three four-week periods.

Design

The study design involved ten Standard Metropolitan Statistical Areas (SMSAs). Two SMSAs received each treatment condition and four served as CONTROL.

To minimize heterogeneity among study areas, only the 81 SMSAs in the Southeast United States were eligible for study. Homogeneity was increased further by excluding SMSAs with populations of fewer than 200,000 (n = 22) and more than 500,000 (n = 21) inhabitants, median age above 36 (n = 4), more than 90 percent White (n = 12), more than 22 percent with four or more years of college and ages 25 or older (n = 4), and density less than 100 or more than 300 per square mile (n = 2). We randomly eliminated SMSAs with overlapping broadcast areas until 10 SMSAs, located evenly throughout the Southeast United States, remained. We divided the Southeast into north, middle, and south, and randomly allocated the SMSAs to treatment conditions within each area. Cost and legal restrictions required two reassignments within area after random allocation. The final distribution of study SMSAs by treatment condition is CONTROL (Chattanooga, Tennessee; Columbia, South Carolina; Jackson, Mississippi; Savannah, Georgia), RADIO (Lakeland, Florida; Macon, Georgia), RPEER (Montgomery, Alabama; Roanoke, Virginia), and RTVPEER (Lexington, Kentucky; Mobile, Alabama).

Data Collection

Cluster sampling procedures identified probability samples of households within each SMSA in 1985.** Households were screened for adolescents ages 12 to 14. For the pretest surveys, conducted from April 1, 1985 through October 13, 1985, interviewers attempted to obtain data from all eligible adolescents and their mothers in the households. When more than one adolescent age 12 to 14 resided in a household, one was randomly selected to serve as a subject. Of the 2,534 adolescent subjects eligible for study in all SMSAs, 2,102 (83.0 percent) participated at pretest. The same subjects were asked to provide data again from April 16, 1987 to October 29, 1987, 11 to 17 months after the broadcasts ended and two to eight months after the mailings for the peer-involvement component ended. Of those who participated at pretest, 1,637 also participated at posttest and are included in the analyses reported here. Some pretest subjects could not be located at follow-up or had substantial missing information and are therefore lost to study. The numbers of subjects across SMSAs range from 132 to 232.

To assess overall attrition bias, we compared subjects who provided data only at pretest with those who also provided data at posttest on the intervening and smoking variables measured at pretest. The two groups did not differ on variables measuring smoking experimentation, subjective expected utility, smoking intention, friend approval of smoking, or friend encouragement of not smoking. Subjects lost to study, compared to subjects who provided both pretest and posttest data, were significantly more likely to be recent smokers (5.0 versus 3.1 percent), to be regular smokers (5.6 versus 3.1 percent), and to have high mean smoking intensity (1.22 versus 1.16).

While collecting posttest data from the panel subjects, we also gathered data from a cross-sectional sample of adolescents 14 to 16 years old and their mothers. Procedures were similar to those used to select subjects at baseline for the panel sample but we used clusters other than those in the panel and fewer subjects. We refer to this as the cross-sectional sample to distinguish it from the panel sample. The cross-sectional sample increased sample size and allowed assessment of testing effects.[9] Of the estimated 1,759 subjects eligible for the cross-sectional sample, 1,216 provided data.

Adolescent subjects averaged one hour to complete a self-administered questionnaire in their homes and provided alveolar breath and saliva samples to measure tobacco use. The mothers of most adolescents also completed a 25-minute self-administered questionnaire and provided alveolar breath samples.

Measures

The variables are listed in the Appendix. Data from the mother questionnaire measured parent education. All other measures are from data provided by the adolescents. Their derivation follows.

Adolescent subjects indicated the likelihood they would experience each of the seven expected consequences of smoking featured in the campaigns (bad breath, difficulty concentrating, loss of friends, trouble with adults, loss of appetite, increased fun, and increased relaxation) and how much they would like or dislike each consequence. We multiplied the responses for each consequence and summed the products to indicate the degree to which more positive or negative consequences of smoking were expected, with the more positive score favoring smoking. This measures subjective expected utility (SEU) for smoking (smoking SEU).[10] SEU for not smoking (nonsmoking SEU) was measured in the same way but the consequences were for not smoking rather than for smoking; more positive scores favored not smoking. A combined SEU (total SEU) was derived by subtracting nonsmoking SEU from smoking SEU; more positive scores on total SEU indicate greater preferences for smoking.

Decreased friend approval of smoking and increased friend encouragement of not smoking were hypothesized to be direct consequences of the peer-involvement component. To measure friend approval, subjects were asked how many of their three best friends would approve of their smoking. To measure friend encouragement, subjects were asked how often someone their own age had encouraged them to be a nonsmoker; response categories ranged from never to 10 or more times. To measure smoking intention, subjects were asked how sure they thought they would smoke in the next two years, with response categories ranging from certain to smoke to certain not to smoke.

Subjects provided alveolar breath samples to measure carbon monoxide (CO); a value ≥ 9.0 ppm indicated recent smoking.[11] Subjects were asked whether they had ever puffed on a cigarette. Sub-

---

**Research Triangle Institute: Survey of Young Adolescent Smoking Behavior: Final report, 1986.

jects also were asked about their smoking intensity using a single questionnaire item that measured recency, frequency, and amount smoked.[12,13] The values ranged from never smoked a cigarette to currently smoke more than two packs a day. We also used the intensity measure to classify subjects as regular smokers if they usually smoked weekly or more often. To increase the validity of self-reports of smoking, subjects were told before beginning the questionnaires that the alveolar breath and saliva samples they gave would be used to measure their smoking.[14,15]

Analysis

Baseline data were used to create subsamples of subjects who were not regular smokers. Of the 1,637 panel subjects, the nine who did not report whether they had puffed on a cigarette were excluded from all analyses. The remaining subjects were divided into those who had not (N = 973) and those who had (N = 655) puffed on a cigarette. Of the adolescents who had not puffed on a cigarette, 22 with missing information on CO or with CO ≥ 9 ppm were excluded; the remaining 951 subjects are nonexperimenters. Of the adolescents who had puffed on a cigarette, 127 who were regular smokers, had CO ≥ 9 ppm, or had missing information were excluded; the remaining 528 are experimenters. The total sample includes experimenters (N = 528), nonexperimenters (N = 951), regular smokers (N = 48), and subjects with insufficient information for classification (N = 110).

Each SMSA was assigned average scores based on the information provided by subjects within the SMSA. Multiple regression analysis for repeated measures was the principal statistical method for inferences concerning treatment differences for changes over time by SMSA, i.e. treatment by time interaction.[16] We did not include control variables in analyses using the SMSA as the unit because these units had small sample size (n = 10), were randomized, and were relatively homogeneous with respect to previously stated population characteristics. Analyses with the individual as the unit used logistic regression for dichotomous dependent variables and linear regression for continuous dependent variables. These latter analyses examined effects for treatment, SMSA nested in treatment, and control variables from the pretest. We included the control variables related to an intervening or dependent variable and to pretest differences between treatments, attrition bias, or missing data substitution. For an intervening or dependent variable at posttest, we controlled for the corresponding pretest measure of the variable.

Results

Independent Variables

Message reach and frequency were estimated by the advertising agency using standard estimating procedures with Arbitron and Nielsen data for radio and television, respectively.[17] The expected consequences messages reached 81 percent of the intended audience an average of 4.5 times during each of the three four-week periods that they were broadcast. The sweepstakes offer in RPEER reached 79 percent of the audience an average of four times. In RTVPEER, messages reached 90 to 94 percent of the intended audience by a combination of radio and television, and they were seen or heard an average of 14 times during the entire period of broadcast. Young people ages 12 to 15 years surveyed by telephone the month after the final campaign messages were broadcast reported higher levels of reach.[18]

Based on sweepstakes entry and US Census data, 21 to 24 percent of the adolescents 12 to 15 years old in RTVPEER entered the sweepstakes; 97.8 percent of them responded to the encouragement of others rather than to the broadcast messages.[8] Nine to 15 percent of the adolescents in RPEER entered the sweepstakes, and 94.8 percent of them responded to their friends rather than to the broadcast.[8]

Intervening Variables

Between pretest and posttest, all intervening variables changed significantly in the expected direction of becoming more favorable toward smoking (Table 1). The p values in Table 1 for the time by treatment interactions indicate whether the change in the intervening variables between 1985 and 1987 varies significantly by treatment. There were significant time by treatment interactions for smoking SEU (nonexperimenters and total sample), nonsmoking SEU (experimenters only), and total SEU (nonexperimenters and total sample).

In Table 2, we show the 1985 and 1987 values of smoking SEU for the total sample, by treatment condition, and measures of treatment effect for change between 1985 and 1987. Smoking SEU increased less in RADIO and RTVPEER than in CONTROL, increased by the same amount in RADIO and RTVPEER, and increased by the same amount in RPEER and CONTROL. These findings suggest that RADIO and RTVPEER had the intended effects of decreasing smoking SEU. These effects of generally 4.0 correspond to about one-third of the baseline standard deviation of smoking SEU, which is comparable to a shift between the median and the 60th percentile. Thus, the campaign effect size is modest rather than large. The findings were similar for the other SEU measures and samples for the statistically significant treatment by time interactions shown in Table 1.

The findings in Table 2 suggest that the peer-involvement component in RPEER might have had undesirable effects, but this seems unlikely given the lower participation in the peer-involvement component in response to RPEER than to RTVPEER. However, to address the possibility of undesirable effects attributable to the peer-involvement component, we disaggregated subjects within RPEER and RTVPEER according to their participation in the peer-involvement campaign. Participants had entered the sweepstakes or reported on their posttest questionnaires that they had been personally contacted to enter the sweepstakes; all other subjects are nonparticipants. We conducted analyses similar to those shown in Tables 1 and 2 using the intervening variables as dependent variables because the campaigns were designed to influence them directly. Within both RPEER and RTVPEER areas, participants did not differ from nonparticipants in their 1985 to 1987 change in SEU or friend approval of smoking, but participants were more likely than nonparticipants to report an increase in encouragement by friends not to smoke. These findings suggest that the peer-involvement component did not produce undesirable effects. The absence of other treatment conditions, such as one with both radio and television broadcast of expected consequence messages and no peer involvement component, precludes analyses that might clarify these findings.

Changes in the SMSAs between 1985 and 1987 other than the campaigns might have produced the higher increase in smoking SEU in RPEER than in RTVPEER and RADIO shown in Table 2. For example, if adolescent use of smokeless tobacco increased more in RPEER than in RADIO and RTVPEER and adolescent use of smokeless tobacco is related to smoking SEU, then the differential change in smokeless tobacco use might explain the smoking SEU patterns. Using the individual as the unit of analysis, we identified intervening

variables other than SEU, and the control variables as measured at pretest, that were related to nonsmoking SEU, smoking SEU, or total SEU at posttest. They were dependent variables in analyses conducted to identify statistically significant time by treatment interactions that parallel the findings involving smoking SEU and total SEU. There were only two statistically significant and parallel interactions, but control for the involved variables did not account for the patterns in Table 2. The greater increase in SEU in RPEER than in RADIO and RTVPEER remains unexplained.

There were significant time by treatment interactions for friend approval of smoking for nonexperimenters and for the total sample (Table 1). The 1985 and 1987 values of friend approval for the total sample, by treatment condition, and measures of treatment effect for change between 1985 and 1987 are in Table 3. These findings suggest that RADIO caused less increase in friend approval of smoking relative to the control condition. The estimated effect of RADIO corresponds to a modest reduction of 7 percent in the number who reported that one or more of their friends approve of smoking. The findings were the same for nonexperimenters.

There were no significant time by treatment effects that involved smoking intention or friend encouragement of smoking.

Cigarette Smoking

Table 4 shows the findings with cigarette smoking as dependent variables. The means of all smoking variables changed significantly between 1985 and 1987 in the expected direction of more smoking. However, none of the p values for the time by treatment interactions were statistically significant. The data are consistent with the conclusion that the campaigns did not influence smoking.

There were substantial within-treatment differences in smoking between SMSAs that must be recognized because they precluded the ability to identify campaign effects for smoking if there were any to be

detected. We began the study with the assumption that 4 percent of adolescent subjects in each study SMSA would be regular smokers and that SMSA changes in smoking within treatment condition would be similar. About 4 percent of our subjects were regular smokers in 1985. However, the range across SMSAs was .6 percent to 5.2 percent. The variation across SMSAs in the other smoking measures, and changes in smoking, also varied substantially across SMSAs. Most importantly, smoking varied substantially among SMSAs within treatment condition. Table 5 shows the treatment-control differences in smoking and the intervening variables that would have been required to achieve statistical significance at the .10 level for powers of .50 and .80 given the SMSA variation in smoking within treatment conditions in our data; the actual differences are also shown. The relatively large error variance for SMSAs within treatment groups clearly precluded detecting campaign effects for smoking. Therefore, whether the campaigns influenced smoking cannot be determined with acceptable certainty from our data.

Related Findings

We also used the 1987 cross-sectional data to examine campaign effects. For each SMSA, we assigned pretest values of the intervening and dependent variables in the panel data to the cross-sectional data. We then conducted multiple regression analysis for repeated measures with a sample size of 20 for the analysis: 10 panel and 10 cross-sectional SMSAs. The main statistic of interest was time by treatment interaction. The conclusions about campaign effects were generally the same as those when only the panel data were used.

Having subjects with and without baseline measures allowed us to identify effects due to the pretest. To assess this, as part of the analyses described in the preceding paragraph, we evaluated the time by treatment by data source (panel versus cross-sectional) interactions involving each intervening and dependent variable. The findings suggest that there were no testing effects.

We also conducted analyses to determine whether campaign effects for smoking varied across selected subgroups by testing for time by treatment by subgroup interactions with multiple regression analysis for repeated measures. The 10 variables used to create the subgroups, each divided at the median except when categorical, were: gender, age, smoking by best friend, smoking by mother, school curricula on smoking, total SEU, alcohol use, parent education, number of hours spent listening to the radio, and number of hours spent watching television. This analysis revealed no pattern that could be interpreted as campaign effects for smoking, and the conclusions for intervening variables remained the same.

TABLE 5—Required and Observed Differences between Treatment and Control

	Required[a] Power		Observed		
Variables	.50	.80	RADIO	RPEER	RTVPEER

Note: SEU = subjective expected utility

a) Differences required to identify effects 50 and 80 percent of the time given study inter-SMSA variance.

b) Overall ANOVAs significant at alpha = .10 (n = 10).

Finally, we conducted analyses of the relationship between treatment and the intervening and dependent variables when using individuals rather than SMSAs as the unit of analysis. This procedure could artificially increase statistical detection of differences by ignoring intra-SMSA correlation among subjects.[19] In these analyses, we controlled for the pretest value of each control variable that was related to the posttest value of the intervening or dependent variable, the pretest value of the intervening or dependent variable being examined, and variables indicating attrition bias and effects from missing-data substitution. The findings were generally the same as when the SMSA was the unit of analysis. SEU effects were limited to RADIO and RTVPEER and no effects for cigarette smoking were detected.

Discussion

SEU and friend approval of smoking appear to have been influenced by the media campaigns. RADIO was as effective for these variables as any of the other more expensive campaigns. The peer-involvement component was not effective. We detected no effect for reducing the onset of smoking, and any potential effect for smoking remains to be demonstrated.

The substantial variation in smoking within treatment conditions is a major methodological limitation of this research because it precluded determining whether the campaigns influenced cigarette smoking. A consideration supporting the possibility of some campaign influence on smoking is that the campaigns appear to have influenced SEU and friend approval of smoking, variables that are related to the onset of smoking.[7,8] In addition, the campaigns featured characteristics that media scholars consider necessary for campaign effects, such as extensive formative research, content based on behavioral science theory, high quality message production, actors with characteristics admired by the audience, and repeated exposure to the campaigns by most of the intended population.[20-22] Earlier studies have found that mass media campaigns can influence behavior.[6]

Some contend that substantial impact by mass media campaigns requires their implementation with other types of interventions, such as community organization efforts or school-based curricula.[2,23] Our study was designed to determine whether the media by themselves are influential. This is the most common and practical application of mass media in public health and, unlike multiple-component approaches, is capable of ready distribution on a national level. However, this also precludes our knowing whether adding other types of prevention programs to the campaigns we designed and implemented would have produced larger effects.

To increase homogeneity of SMSAs within and across treatment conditions, we limited our study to SMSAs in the Southeast US, included only SMSAs similar on social and demographic characteristics, stratified the Southeast by area, and randomly allocated SMSAs to treatment conditions within area. Still, substantial variation in adolescent smoking precluded our determining whether there were campaign effects for smoking. We might have avoided the problem by studying a much larger sample of SMSAs and perhaps matching them for baseline smoking behavior before random allocation to treatment conditions.

Information on other interventions that might have been implemented to influence adolescent smoking in our study areas would have been useful for attempting to explain and control the SMSA variation in smoking. We assume that school-based programs would have been the only potentially significant organized activities implemented to reduce adolescent smoking during the time of our study; we controlled for school curricula and many other variables at baseline when using the individual as the unit of analysis. The substantial variation in adolescent smoking by SMSA, and our findings on effect size for intervening variables, suggest that more powerful interventions than the mass media campaigns we implemented might be necessary to demonstrate community-level behavioral effects for programs designed to prevent adolescent smoking.

We designed the peer-involvement component to influence perception of friend approval of smoking. However, the findings suggest that only RADIO, which did not have a peer involvement component, influenced friend approval. Perhaps RADIO influenced peer approval because two of the expected consequences messages focused on peers. Or, perhaps the radio messages were projected to their friends because they are like the young people who recorded them. The reason this effect did not also occur in response to RPEER and RTVPEER was not determined.

Given the centrality of personal influence to many behavioral science and mass communication theories, it is significant that the two campaigns with the peer-involvement component, RPEER and RTVPEER, were not more effective than RADIO. Perhaps the personal contact produced by the peer-involvement component was too superficial for impact, perhaps this approach is less powerful than commonly believed, or perhaps effects would have appeared for younger or older people. We do not have the data required to assess these possibilities.

Implementing the campaigns in 1985 for a broadcast reach of 75 percent of the United States population 12 to 17 years old under the conditions of our field experiment, excluding development and research expenses, would have cost $1,843,000 for RADIO, $12,866,000 for RPEER, and $28,944,000 for RTVPEER. Although radio is the less expensive medium, television is the broadcast medium that receives the most attention by those who design, implement, and evaluate mass media campaigns. Perhaps the glamour associated with television explains why there have been few recent studies of health-oriented radio campaigns. Radio use increases relative to television use during adolescence,[24] and our findings suggest that radio should be given more attention in campaigns to influence adolescent smoking and by research on campaign effectiveness.

Although findings that demonstrate program impact for intervening variables such as SEU and friend approval but not for behavior can sometimes be dismissed readily, one can also argue that they merit attention. SEU for smoking and friend approval for smoking have been considered by many to be precursors of smoking.[7,8] Our findings suggest that RADIO did influence SEU and friend approval. These findings, together with the capability of radio campaigns to be implemented readily on a national scale or to other large populations at lower cost than virtually any other type of intervention, support its potential role for health promotion among adolescents. Whether adolescent smoking would be influenced by our radio campaign or by others, however, has yet to be shown. The failure of the more expensive components, television broadcast and peer involvement, to influence the intervening variables suggests that these components might be unworthy of further consideration, at least as they were implemented in our research.

Our findings cannot be generalized to all applications of the mass media to smoking prevention. We might have found other effects if we had done things differently, such as focused on younger or older adolescents, implemented the campaigns in smaller or larger communities, or also implemented smoking prevention curricula in schools. The effects also might have been different if we had used other theories for guidance and if the style and format of our messages had been different. Flay, *et al*,[25] and Worden *et al*,[26] describe other approaches to using the mass media to prevent adolescent smoking. Finally, our findings cannot be generalized to the many public service campaigns that rely solely on donated broadcast time and fail to reach most of their intended audiences. ☐

Acknowledgments

This research was supported by Grant CA38392 from the National Cancer Institute of the National Institutes of Health. Elizabeth S. Bryan and Lynn A. Fisher contributed substantially to the methods used in this research and to the design of the mass media campaigns; John M. Sweeney played a major role in the creation of the mass media messages; Elizabeth Turney conducted some of the analyses reported in this paper. This paper reflects comments on earlier drafts by Susan Ennett, Robert L. Flewelling, Dr. Vangie A. Foshee, and Harm Hospers. Dr. Gayle Boyd, Dr. Thomas J. Glynn, and researchers funded by the same program of the National Cancer Institute provided advice and assistance throughout the conduct of this research.

APPENDIX—Intervening, Dependent and Control Variables

Intervening

- Smoking subjective expected utility
- Nonsmoking subjective expected utility
- Total subjective expected utility
- Friend approval of smoking
- Friend encouragement of not smoking
- Smoking intention

Dependent

- Smoking experimentation
- Smoking intensity
- Regular smoking
- Recent smoking

Control: Background

- Gender
- Race
- Age
- Parent education
- Years residence in area
- Father presence

Control: Parent and Friend Smoking

- Mother approval of adolescent smoking
- Smoking by mother
- Smoking by three best friends
- Smoking by best friend

Control: General Social and Psychological

- Popularity
- Rejection
- Egotism
- Social passivity
- Reputation
- Femininity
- Self-deprecation
- Depression
- Boredom
- Sensation-seeking
- Deviance
- Rebelliousness
- Religious involvement
- Risk-seeking
- Locus of control
- Impulsivity
- Closeness to mother
- Peer versus parent influence

Control: Media Use

- Number of hours listen to radio
- Number of hours watch television

Control: Exposure to Antismoking Interventions

- Advertisements
- School curricula

Control: Other

- Smokeless tobacco use
- Alcohol use*

A Comparison of Injury Death Rates in China and the United States, 1986

Guohua Li, MB, MPH, and Susan P. Baker, MPH

ABSTRACT

Background: The importance of injury as a public health problem is not well recognized in many developing countries. Data have recently become available on injury mortality in China.

Method: We compared Chinese injury data based on a 100 million population segment for 1986 with data for the United States.

Results: The age-adjusted death rate from all injuries for China exceeds the rate for the US (69.0 vs 61.3 per 100,000). The US has higher death rates from motor vehicle crashes, fires, and homicide; China has greater mortality from drowning, poisoning, falls, and suicide. Especially noteworthy in China are the high drowning rates among young children and the elderly and the high suicide rates in rural areas among young adults and the elderly.

Conclusion: Injury is an important public health problem in China, exceeding in many respects the problem in the United States. It is urgent for China to place high priority on injury research and prevention. (*Am J Public Health* 1991;81:605–609)

Introduction

Injury is now well recognized in the United States and other developed countries as an important public health problem, the leading cause of death from the first year of life to age 44.[1] Most efforts and achievements are limited to the US and other industrial nations. In developing countries, injury research is still in its infancy.

The People's Republic of China, with about one-fifth of the world's population, reflects many aspects of other developing countries. The authors compared the injury death rates in China and the United States to determine whether the great differences between China and the US in their social, economic, and cultural background are associated with major disparities in injury death rates.

Methods

China does not have a complete nationwide disease and injury surveillance system. Data on mortality have become available since the early 1980s with the development and extension of the disease surveillance points (DSP) in its 30 provinces, covering about 100 million population or about 10 percent of the total population of the country. The 1986 DSP injury data for China were provided by the World Bank and are published in summary form.[2] Data for the US come from the National Center for Health Statistics (NCHS).[3] Both sets of data are based on the Ninth Revision of the International Classification of Diseases.

Results

Crude and Age-adjusted Death Rates

The US has a higher crude death rate than China for all injuries combined, but the Chinese rate is higher when adjusted to the 1986 US population (Table 1). The death rates from falls and suicide for China increase significantly after adjustment, as rates from these causes are very high for the elderly and the American population is older than China's. Chinese age-adjusted death rates from falls, drowning, and suicide are two to four times the US rates.

For all injuries, the US demonstrates much greater gender differences. In US males, the age-adjusted rate is 2.7 times the rate for females. In China, the male rate is only 1.1 times the female rate.

Percent of Injuries by Cause

The top three causes of injury death in China are suicide, motor vehicle crashes, and drowning, which account for 33 percent, 16 percent, and 14 percent of all injury deaths, respectively (Figure 1). Motor vehicle crashes, suicide, and homicide are the leading causes of injury death in the US, accounting for 31 percent, 20 percent, and 14 percent of all injury deaths, respectively. The prominence of falls, poisoning, and suffocation is similar in the two countries.

Death Rates by Cause and Area

In both China and the US, urban areas have higher death rates from poisoning and falls while rural areas have higher death rates from fires/burns and drowning. For these causes, the urban/rural pattern differs markedly between the coun-

TABLE 2—Crude Death Rates from Injury by Cause and Area, in China and US*

	China (1986)		US (1980–1986)	
Cause	Urban	Rural	Central Cities	Remote Rural
Motor Vehicle	8.4	8.6	17.0	29.2
Poisoning	2.7	2.4	3.0	1.9
Falls	6.7	4.6	6.6	3.9
Fires/Burns	0.7	1.4	2.6	3.6
Drowning	4.0	12.7	2.0	5.9
Suffocation	0.6	3.1	0.4	0.6
Suicide	10.0	27.7	13.6	12.7
Homicide	1.6	1.2	17.7	5.4
All Injuries	41.4	71.0	73.4	80.7

*Source: Baker SP, et al.[10]

tries. In the US, homicide rates are very high in large cities and motor vehicle death rates are high in rural areas. Suicide rates, on the other hand, are similar in urban and rural areas of the US, while in China the rates in rural areas are almost three times the urban rates (Table 2).

Death Rates by Age and Sex

All Injuries: China has higher death rates at ages 0–14 and above 55 years, while the US has higher death rates at ages 15–54 (Table 3). The greatest disparity is at the two extremes of age; for children under one year the death rate in China is almost five times the US rate, and for age 85 and older, the rate is 2.5 times the US rate. For both countries there is a peak at ages 20–24 and a sharp rise after age 65. For males, the peak at ages 20–24 is more extreme in the US, where death rates exceed the Chinese rates from ages 15 to 59. In contrast, death rates for Chinese females are consistently higher than those for US females, except at ages 25–29. There is a pronounced peak in the death rate at ages 20–24 for Chinese females, but not for US females.

Motor Vehicle Crashes: Motor vehicle death rates in the US are more than double the rates in China for both males and females ages 10 to 29 (Figure 2). A peak at ages 15–24 characterizes the American death rates for both sexes. Otherwise, death rates increase fairly steadily throughout the life span in both countries.

Poisoning: High-risk populations for poisoning in China are infants (under one year) and the elderly (above 60 years), and the peak appears at age 85 and over for both males and females. In the US, the death rate also increases in the elderly, but is highest in males in their thirties.

Falls: In both China and the US, the high-risk population for falls is the elderly. Falls are the leading cause of fatal injury among ages 65 and above for both males and females in the two countries. The death rates for males at age 85 and above are 301.7 and 163.1 per 100,000 in China and the US, respectively. For females, the corresponding figures are 404.4 and 121.8. The Chinese rates are more than four times the US rates for children less than 15 years old.

Fires and Burns: Americans have higher death rates from fires and burns before age 70 than Chinese. However, Chinese rates are higher after age 70 than American rates. Notably, the US death rate from fires and burns under age five is more than twice the Chinese rate for both males and females.

TABLE 3—Death Rates from All Injuries by Age and Sex, in China and US, 1986

		<1	1–	5–	10–	15–	20–	25–	30–	35–	45–	55–	65–	75–	85+
Male	China	141	63	36	24	42	68	44	54	58	56	79	143	285	671
	US	33	27	16	23	102	141	121	107	93	87	88	110	209	422
Female	China	141	48	15	12	39	57	29	32	33	37	56	108	277	692
	US	30	19	9	10	34	34	30	27	26	28	32	46	95	221

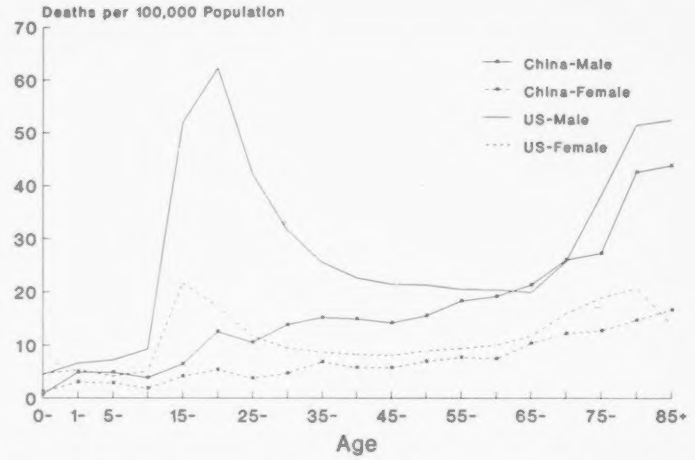

FIGURE 2—Death Rates from Motor Vehicles by Age and Sex in China and US, 1986

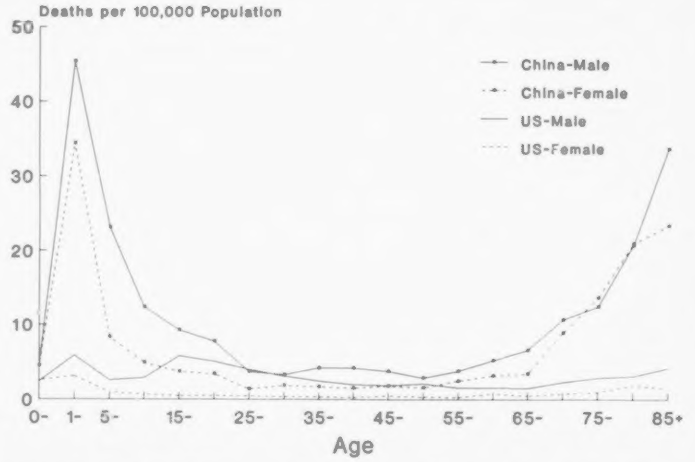

FIGURE 3—Death Rates from Drowning by Age and Sex in China and US, 1986

Drowning: Drowning is the third leading cause of injury death in China. The drowning rates at ages 1–4 for China are 45.4 and 34.4 deaths per 100,000 for males and females, respectively (Figure 3), seven to 10 times the American rates. Except for males ages 25–29, China has higher death rates from drowning for both males and females than the US.

Suffocation: Suffocation accounts for about 3 percent of all injury deaths. In infants, the rates in China are 19 times and 31 times the US death rates for males and females, respectively. Above age 85, on the other hand, the US rates are 42 times and 12 times the Chinese rates for males and females, respectively. In most other age groups the two countries share very low death rates from suffocation.

Suicide: Suicide is the leading cause of injury death in China and ranks second in the US. For males, China has lower death rates before age 60 and higher rates after age 60 than the US (Figure 4). For Chinese females, the suicide rate is more than 10 times the US rate at ages 15–24 and after 60, and more than twice the US rate for ages 25–59.

Homicide: In contrast to suicide, homicide is a major killer only for Americans. For each sex and age group, the US has higher homicide mortality (Figure 5). In both countries, male death rates are two to three times the rates for females. For the US, homicide rates are highest in the twenties and then decline until the sixties. For children less than 5 years old, the homicide rate in the US is more than four times the rate in China.

Discussion

Injury mortality data for China have not previously been described in detail. The general profile of injury death rates in China differs profoundly from the US. China's age-adjusted mortality from all injuries surpasses that of the US, even though its crude rate is lower than the US rate. In particular, China has higher death rates from falls, drowning, and suicide, and the US has higher rates from motor vehicles, fires and burns, and homicide.

Although the population-based death rate from motor vehicles in the US is twice as high as in China, there is evidence that China does not have safer transportation than the US. On average, China has about 15 motor vehicles per 1,000 population, which is less than a fortieth of the US ratio.[4,5] Its death rate per 100,000 motor vehicles is more than 10 times the rate of the US. The mortality from motor vehicles in China has been rising in the last 10 years[4] while declining in the US and other industrial nations.[6,7] With industrialization of China, death rates will continue to rise and the tragedy experienced by developed countries will be repeated, unless China pays enough attention to highway safety research and learns lessons from developed nations.

The very high suicide rate in China observed among ages 15–24, and among females age 60 or older, reflects many so-

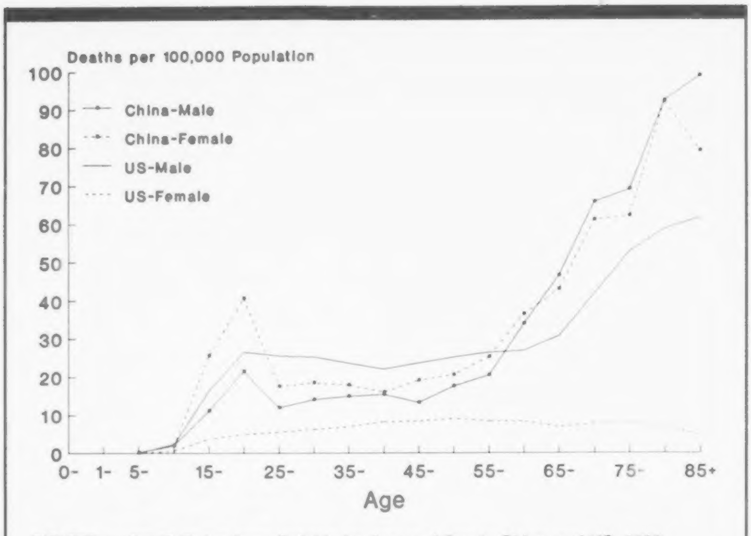

FIGURE 4—Death Rates from Suicide by Age and Sex in China and US, 1986

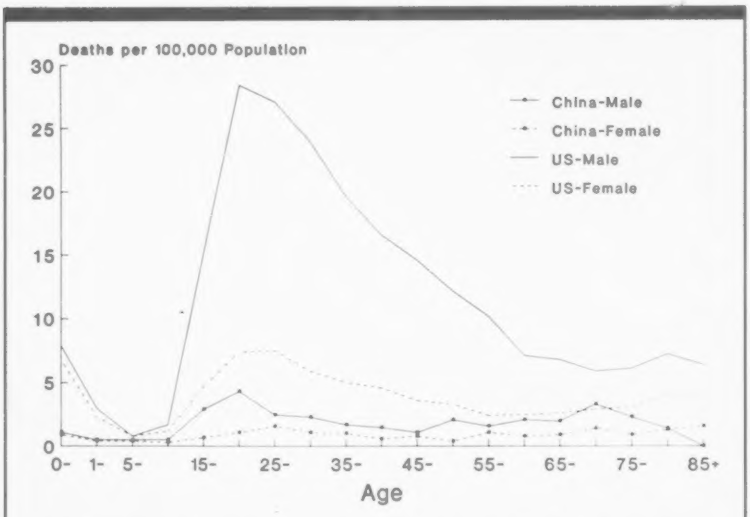

FIGURE 5—Death Rates from Homicide by Age and Sex in China and US, 1986

cial and cultural problems that China is facing. The motivation and cause of suicide may be greatly different between Chinese and Americans. For young Chinese females, especially those living in rural areas, marriage problems and poverty may be the major causes of the high suicide rate. For Chinese females at ages 20–24, the suicide rate is as high as the motor vehicle death rate for the American males in the same age group. In this age group, the suicide rate among females in rural areas is five times the rate in urban areas (78.3 vs 15.9/100,000). Similarly, for Chinese males ages 20–24, rural areas have four times the suicide rate as urban areas (40.7 vs 9.9/100,000). For Chinese elderly, poverty, long-term disease, and the decrease of traditional family relationships may contribute to the extremely high suicide rates. In the US, on the other hand, the suicide rate is highest in large cities and lowest in very rural areas. Because of the very complicated factors influencing suicide, China, as other countries, may have even greater difficulty in reducing its high suicide rates than in controlling its rising mortality from motor vehicles.

In contrast to suicide, the US has much higher homicide rates than China for each sex. Firearms are the weapon most commonly used in American homicide.[8,9] The law prohibiting individual ownership of firearms and virtual eradication of drug abuse may be major contributors to the relatively low homicide rate in China. On the other hand, even the non-firearm homicide rate in the US is substantially higher than China's total homicide rate, suggesting the important contribution of other factors.

Drowning is the third leading cause of injury death in China. Its major victims are young children and the elderly. Drowning rates in the US are highest at ages 1–3,[10] but are much lower than in China. One of the most effective interventions is barriers for swimming pools, which could reduce about 70 percent of childhood drownings in pools.[11] As drowning occurs in ponds, lakes, rivers, and other natural settings in China, to prevent and reduce the incidence is very difficult. In some rural areas of south China, drowning is the leading killer of children at ages 1–7.[12]

Among all injuries, falls exhibit the most similar profile in the two countries, although China has higher death rates at each age. Studies show that effective measures can reduce the incidence for children.[13,14] The higher death rates in China from falls in the elderly may reflect poor access to medical care, since mortality from falls often results from complications following relatively minor injury and has been greatly reduced in the US in recent years.[10]

Although the injury data for China are reasonably valid, some problems affect our comparison. First, about 80 percent of the Chinese population live in rural areas, but the rural population in the disease surveillance points sample accounts for only 43 percent. This should greatly underestimate the total death rate from all injuries in China, since the rate is much higher in rural areas than in urban areas. In particular, it leads to an underestimation of China's suicide and drowning rates, which are especially high in rural areas. Second, as ICD-9 has not been widely used in China, some misclassifications probably exist, and it is difficult to determine the degree of misclassification. Even so, our results suggest that injury is a serious public health problem in China that merits high priority. Special studies and injury surveillance systems that will provide details on the circumstances of injury are needed, followed as soon as possible by implementation of programs for effective injury prevention. □

Acknowledgments

We thank J. Richard Bumgarner of the World Bank for providing the data on injuries for China that stimulated development of this paper. This research was supported by Centers for Disease Control Grant No. R49/CCR302486-05 from the Division of Injury Epidemiology and Control, Center for Environmental Health and Injury Control.

Core Curriculum on Tuberculosis Available through CDC

A training document on tuberculosis is now available through the Centers for Disease Control (CDC). The document was developed as part of the National Tuberculosis Training Initiative (NTTI) which was implemented in 1989 by the Division of Tuberculosis Control of CDC, the American Thoracic Society, and over 22 national professional medical and nursing associations including the American Public Health Association. Increasing the knowledge of health care providers about tuberculosis is a critical element in the Strategic Plan for the Elimination of Tuberculosis in the United States, which was recently endorsed by APHA.

The "Core Curriculum on Tuberculosis" contains information on epidemiology, transmission and pathogenesis, screening and prevention, diagnosis, treatment, infection control, and public health aspects of tuberculosis. It includes information on managing patients with coexisting human immuno-deficiency virus (HIV) infection. It is intended for use in developing educational programs as well as serving as a reference manual for health care providers caring for persons with or at risk of clinically active tuberculosis and tuberculous infection.

Copies may be obtained by writing to: Ms. Landis Brown, Technical Information Services, Center for Prevention Services, Centers for Disease Control, Mailstop E-06, Atlanta, GA 30333. Members of the American Public Health Association should identify themselves as such.

A slide series has been developed to accompany the "Core Curriculum on Tuberculosis." This series may be obtained on loan (and duplicated) from your State tuberculosis control program.

Comparison of Two Growth Charts in Lesotho: Health Workers' Ability to Understand and Use Them for Action

ABSTRACT

Background: Two growth monitoring charts widely used for growth monitoring in Africa (the Road-to-Health (RTH) and the Growth Surveillance (GS)) were compared in order to assist the Government of Lesotho to decide on an appropriate national growth chart.

Methods: Thirty-four health workers were taught and tested on the RTH during a first week of training and on the GS during a second week (the RTH-GS group), while the order was reversed for another 25 trainees (the GS-RTH group). The health workers were trained and tested on their ability not only to use and interpret the two charts, but also to make the right decisions about specific actions to be taken when growth faltering occurs.

Results: There was no difference between scores to the RTH and GS charts after one week of training. After the second week of training, the scores to the RTH chart improved and became better than those to the GS chart. The scores to the GS test did not increase with previous knowledge of the RTH chart.

Conclusions: For this reason and others discussed in the paper, the RTH chart was recommended for nationwide use in Lesotho. The adoption of this recommendation was facilitated by the close involvement in this research of public and private agencies responsible for growth monitoring in Lesotho. Introduction

Growth monitoring has been promoted by international agencies and local governments as one of the principal activities to combat malnutrition among young children in developing countries.[1,2] Growth charts are used

- as an educational and promotional tool, i.e., to make the dynamic process of growth visible to both health workers and mothers and to motivate them to take action to improve or maintain the child's nutritional status[3] and
- as a screening tool to allow the early detection of growth faltering in children and the targeting of appropriate interventions.[4]

Four conditions are necessary for growth charts to be useful for either educational or screening purposes. First, the child's age and weight data must be reasonably accurate. Second, health workers must be able to understand and interpret growth charts properly. Third, once growth faltering is detected, health workers must be able to identify the appropriate actions that need to be taken. Fourth, mothers must also be able to understand the growth charts and the messages provided by the health workers. The second and third issues are addressed in the present paper and the fourth one is discussed elsewhere.[5]

In Lesotho, a small kingdom surrounded by the Republic of South Africa, the concern about health workers' and mothers' ability to understand growth charts originated from the widespread use of two different charts throughout the country. The Ministry of Health, which administered approximately one-third of the Primary Health Care clinics, was using the World Health Organization (WHO)[6] version of the Road-to-Health chart (Figure 1). The remaining clinics were administered by the Catholic Relief Services and used the Growth Surveillance system.[7] This system consists of two charts: the Master Chart (Figure 2A), retained at the clinic for statistics compilations and the Growth Surveillance chart (Figure 2B), taken home by mothers.

In Lesotho, both charts had strong proponents. Those advocating the Growth Surveillance chart emphasized the fact that this chart had been developed in Africa and was more socially and culturally acceptable for African health workers and mothers. Although the superiority of this chart over the Road-to-Health had never been tested, it was assumed that, for Africans, a straight flat line would be a better graphical representation of adequate growth (regular weight increase) than an ascending slope. On the other hand, the proponents of the Road-to-Health chart felt that African mothers were not different from other mothers in understanding a positive slope as representing adequate growth and a negative slope as a sign of weight loss. Furthermore, proponents of the Road-to-Health chart felt that it was easier for health workers to learn and

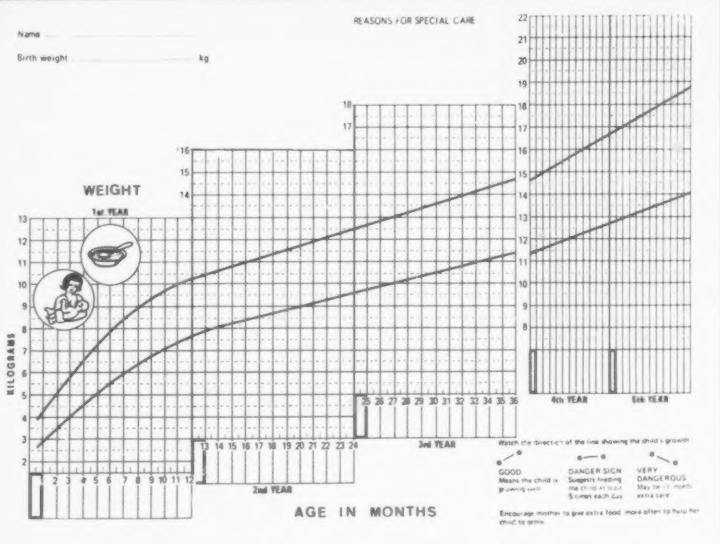

FIGURE 1—The Road-to-Health (RTH) Chart

interpret than the Growth Surveillance chart. UNICEF fostered this study to resolve these differences of opinion.

A Steering Committee, composed of members from various institutions involved in growth monitoring in Lesotho (see Appendix I for the list of participating institutions), was formed to advise the Government of Lesotho in the choice of a single growth chart to be used uniformly throughout the country. The final decision was to be based on the result of two studies, one that assessed health workers' ability to understand and use the charts for decision making (present study) and one that compared mothers' understanding of the two charts.[5] This Committee was involved in discussions and decisions about the various aspects of the research, including setting the objectives, choosing the experimental design, and developing the questionnaires and testing instruments. It also participated in the development of "Guidelines for Action", i.e. guidelines for decisions to be taken from the results of a weighing (Appendix II). Finally, the Steering Committee played a crucial role in facilitating implementation of the study in the field and in reviewing the results and discussing the inferences and implications for the country.

The objectives of the present study were to evaluate health workers' understanding and skills in using and interpreting the two growth charts after one week of training in each one, and in using the information for counseling and referral decisions according to the actions the Committee felt were indicated.

Methods

Study Sample and Design

Fifty-nine health workers from four hospital training centers of Lesotho were included in the study. Each participant was taught the two charts on two consecutive weeks.

A cross-over design was used to examine and take into account possible carry-over effects occurring when the learning of a chart taught second is made easier by the knowledge of the first chart. Therefore, two different treatment sequences were used and training centers were randomly assigned to either one: Hospitals A and B were taught the Growth Surveillance chart first and the Road-to-Health chart second (GS-RTH group), while Hospitals C and D were reversed and taught the Road-to-Health chart first and the Growth Surveillance chart second (RTH-GS group).

Growth Charts Used

The two charts compared were the RTH (Figure 1) and the GS (Figure 2B) chart. On the RTH chart, weight in kilograms forms the vertical axis and age of the child in months (ranging from 0–60 months) is on the horizontal axis. Two curves are printed on the chart and delimit the "Road-to-Health" zone. The upper one represents the median values for the reference population (50th percentile of the National Center for Health Statistics standards for boys[6]) and the lower one represents the NCHS third percentile for girls.[6] The GS chart contains the *percentage* of median weight-for-age (using the Harvard standards)[7] on the vertical axis and age in months on the horizontal one. Thus a straight line on this chart represents a child whose growth continues at a constant percentage of the standard weight-for-age. A green horizontal band (black in Figure 2B) delimits the so-called zone of "adequate growth" which corresponds approximately to the "Road-to-Health" on the RTH chart. A Master Chart (Figure 2A) must be used before plotting the data on the GS chart to find the corresponding percentage of standard weight-for-age for each child.

The decisions to be taken after weighing a child as developed by the Steering Committee (Appendix II) were also taught and used in the final test to assess the health workers' ability to use the charts for decision-making.

Teaching and Testing Procedures

One experienced teacher, who had been trained by the Catholic Relief Service and the Ministry of Health staff on the GS and the RTH charts, respectively, conducted all the teaching sessions. The format of the lecture on each chart had been standardized so that the amount of time spent on each aspect of the chart was the same for both. All lectures were taped and reviewed by the project director (MR) to ensure uniformity of content and lack of bias in the teaching.

On their first day, all participants were tested on their knowledge and understanding of both charts (baseline test) and information was collected on their previous exposure to the charts and work experience in primary care clinics. Each week of training in each chart consisted of approximately six hours of theory and six hours of practice. The training was done in a classroom setting using case histories. The trainees were instructed on how to calculate age given the date of birth (using a standard technique), how to plot hypothetical weights on growth charts, how to interpret growth curves, and what decisions to make (see Appendix II: Guidelines for Action).

The participants' knowledge, interpretation of the chart, and ability to make the appropriate decisions as prescribed by the Guidelines for Action were tested at the end of each training week: The final tests (one for the RTH and one for the GS)

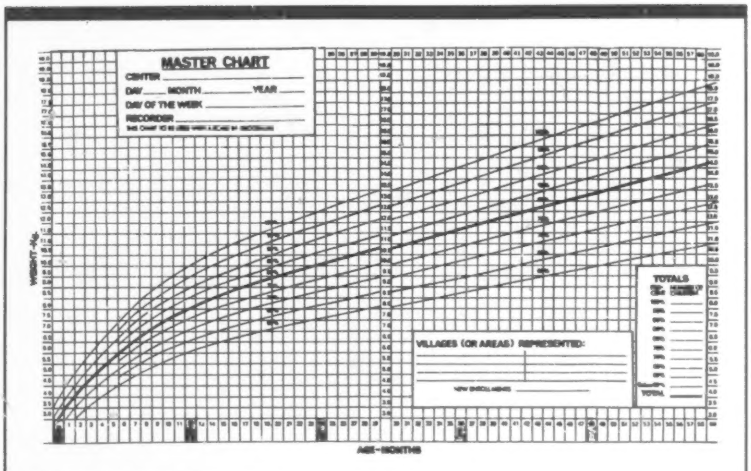

FIGURE 2A—The Master Chart

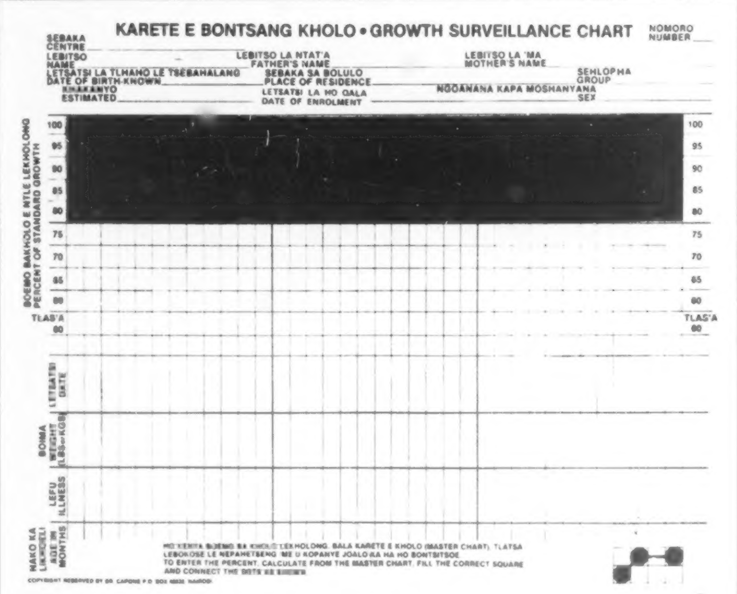

FIGURE 2B—The Growth Surveillance (GS) Chart

were very similar in their format and degree of difficulty. They were composed of case histories with questions on: age calculation, plotting of weights on the charts, interpretation of growth charts, and ability to use the Guidelines for Action.

Analytical Methodology

The total scores to the final tests as well as their different components were compared using t-tests, and confidence intervals were calculated using standard techniques.[8] The multivariate analysis of variance procedure (MANOVA)[9] was used to test main effects (chart, teaching period, training center) and interactions (particularly the carry-over effect, or treatment by period interaction); to control for baseline scores, age calculation scores and inter-hospital variability (using a nested design); and to obtain adjusted means and standard errors. The data were coded, entered and analyzed in Lesotho, using the Lesotho Food and Nutrition Coordinating Office (FNCO) microcomputer facilities, and the SPSS/PC+ statistical package.

Results

The overall score to the baseline test on growth charts knowledge was 3.4 out of 10 possible points and did not differ between training centers. Although work experience varied between participants (from 0 to 48 weeks), their poor knowledge of growth charts suggests that they had never received proper training in either chart.

A positive carry-over effect was found in the ANOVA model (significant interaction between chart and teaching schedule), meaning that prior training in one chart facilitated the learning of the second chart. Due to these findings, comparisons between the charts are presented separately for first training and for second week training.

Table 1 shows the results of the tests after training for all participants grouped by hospital and training schedule. In spite of similar baseline results, some differences between training centers were observed in the final scores. On average, Hospital B had higher scores than the other training centers, for both final tests, while Hospital C had lower scores. To control for the hospital variability, further analyses were done by analysis of variance (MANOVA procedure[9]), using a nested effect model (hospital within training schedule group). The baseline scores were also included in the model as covariates to adjust the final scores. The results of this analysis are presented in Table 2, which shows a comparison of the RTH and GS scores (unadjusted and adjusted) obtained on first week training and upon second week training, for the four hospitals grouped by training schedule. On first week training, the difference between the charts was minimal. Upon second week training, however, the scores to the RTH test were 15–20 percent higher (adjusted and unadjusted means, respectively) than the scores to the GS chart. This large difference between the charts resulted from a positive carry-over effect from first to second week training, observed only when the RTH chart was taught second: the GS-RTH group improved their score markedly from the first to the second week of training (+5.82, unadjusted means), while the RTH-GS group decreased their score from the first to the second week of training (−.76, unadjusted means). Examination of the components making up the total score to the final tests reveals that most of the carry-over effect seen in the GS-RTH group was due to the marked improvements in the interpretation and action questions (Table 1, Hospitals A and B).

TABLE 1—Results of the Final GS and RTH Tests, by Hospital and Training Schedule[a] (Group)

	GS Test				RTH Test			
Group/Hospital	Age[b]	Plotting[c]	Interpretation/ Action[d]	Total	Age	Plotting	Interpretation/ Action	Total

Hospital A	4.54	3.45	25.15	33.16	4.46	4.46	31.92	40.84
	(1.13)	(1.27)	(8.63)	(9.67)	(1.39)	(0.88)	(5.63)	(6.52)
Hospital B	4.00	4.00	33.90	41.90	4.09	4.38	38.09	46.57
	(0.95)	(1.00)	(6.47)	(7.30)	(1.73)	(1.28)	(3.05)	(4.33)
A + B	4.20	3.79	30.56	38.56	4.23	4.41	35.73	44.38
Pooled	(1.04)	(1.12)	(8.43)	(9.22)	(1.60)	(1.13)	(5.14)	(5.90)
Group 2: RTH-GS[e]								
Hospital C	3.10	2.30	23.50	28.90	3.50	3.20	24.00	30.70
	(1.52)	(1.70)	(8.42)	(11.03)	(0.97)	(1.50)	(8.31)	(9.47)
Hospital D	3.67	2.80	30.20	36.67	3.73	4.06	28.93	36.72
	(1.59)	(1.57)	(9.06)	(11.07)	(1.62)	(1.28)	(8.80)	(10.38)
C + D	3.44	2.60	27.52	33.56	3.67	3.72	26.96	34.42
Pooled	(1.56)	(1.61)	(9.26)	(11.50)	(1.38)	(1.43)	(8.79)	(11.50)

[a] The sample sizes were: Hospital A (n = 13), Hospital B (n = 21), Hospital C (n = 10), Hospital D (n = 15).
[b] Age: Calculation of age (maximum score = 5 points). Method was the same for both charts.
[c] Plot: Plotting of weights on charts (maximum score = 5 points).
[d] Interpretation and action: Interpretation of growth patterns and decision about actions to be taken, using the chart-specific Tables of Action (maximum score = 41).
[e] GS-RTH: GS taught first; RTH-GS: RTH taught first.
NOTE: The numbers in this table are means with standard deviations in parentheses.

Age calculation scores, on the other hand, did not improve from first to second training, but differed between hospitals, following a similar pattern as that observed for the overall scores. Since age calculation was independent of the charts, the differences observed between hospitals reflected variations in intrinsic learning capabilities of the health workers. An analysis of the sum of the interpretation and action scores was done that controlled for both hospital variability (using the nested design described previously) and differences in learning capability as proxied by age calculation confirmed the inferences drawn from Table 2. There was no substantial difference between the scores of the RTH and GS charts, −2.17 (with 95% confidence intervals (CI) of −6.67 to 2.33) after the first week of training. A significant improvement in the adjusted interpretation and action score from 31.81 ± 1.28 (standard error) to 38.16 ± 1.11 occurred when the RTH was taught in the second week. This contrasted with no improvement (from 33.98 ± 1.84 to 33.86 ± 1.59) when GS was taught in the second week. Thus the final adjusted score for interpretation and action was 4.3 (with CI of .43 to 8.17) in favor of RTH after the second week of training.

Discussion

In contrast to a previous study that tested health workers' skills in using different growth charts,[10] our study standardized the educational input across charts, and the participants were tested not only on their ability to understand, use, and interpret growth charts but also on their skills in using the Guidelines for Action to make the right decisions about a particular child. These guidelines were developed by Basotho experts involved and experienced in growth monitoring and maternal and child care. The feasibility in actual field conditions of implementing the actions proposed was an important consideration in the creation of these guidelines.

The present study had two major findings. First, at the end of the first train-

TABLE 2—Mean Scores to the GS and RTH Tests, by Group (Schedule of Training) and Week of Training[a]

	Results to the Final Test on		Difference between Charts
	GS Chart	RTH Chart	Difference (95% CI[b])
First week training			
	Group 1: GS-RTH (Hospitals A and B)	*Group 2: RTH-GS* (Hospitals C and D)	
Unadjusted means	38.56	34.32	+4.24 (−.84,9.32)
(SE)	(1.58)	(2.06)	
Adjusted means[c]	37.41	35.57	+1.84 (−3.94,7.63)
(SE)	(1.67)	(2.36)	
Second week training			
	Group 2: RTH-GS (Hospitals C and D)	*Group 1: GS-RTH* (Hospitals A and B)	
Unadjusted means	33.56	44.38	−10.82 (−5.90,−15.74)
(SE)	(2.30)	(1.01)	
Adjusted means[c]	36.04	43.77	−7.73 (−2.46,−13.00)
(SE)	(2.20)	(1.55)	

[a] Sample sizes were: group 1 (n = 34) and group 2 (n = 25).
[b] 95% confidence interval.
[c] The means were adjusted for hospital variability and for baseline scores, using the MANOVA[9] procedure and a nested design model (hospital within group).

ing week, the health workers who were taught the RTH understood their chart as well as those who were taught the GS chart. Thus, the argument that the GS was easier to learn for inexperienced African health workers was not substantiated. Second, when the participants were taught a second chart, those taught the RTH chart scored approximately 15 percent higher than those who were taught the GS chart. This improvement was not observed when the schedule of teaching was reversed: RTH first and GS second.

The improvement when RTH was taught second was achieved mainly through higher scores in the interpretation and action questions which measured the health workers' ability to identify appropriate interventions to be given to hypothetical children from the case histories. Since the guidelines were almost identical for the two charts,* it was expected that participants would master them better at the end of the second week, irrespective of the teaching sequence. However, our results showed no improvement on these questions and in the total score for those taught the GS chart on the second week (RTH-GS group). This finding suggests that prior knowledge of the RTH did not facilitate the learning of the GS chart and may even have confused the trainees because the visual presentation of growth in the GS chart is counterintuitive.

This finding is important since it is related to a situation that exists in many African countries: health workers that have been using a RTH-type chart for many years have to change to the GS system when the Catholic Relief Service Food and Nutrition Program is introduced; this requires intensive retraining of all the health workers. If the prior knowledge and experience with another chart (in this case the RTH) did facilitate the learning of the GS chart, the whole effort involved in the change of system would be reduced and potentially justifiable. However, the results of our study suggest that this was not the case in Lesotho.

Therefore, our conclusion from this study is that, in Lesotho, the RTH would be a better choice than the GS chart for two reasons. First, since health workers could learn and understand the RTH as well as the GS chart after the first week of teaching, it would be an appropriate chart for training inexperienced people. Second, and more important, in the context of Lesotho where retraining is a crucial issue, the RTH chart would be superior since second week training on the RTH improved the scores of those previously trained in the GS chart.

These recommendations are in accordance with those made in a concurrent study[5] showing that mothers who were taught the RTH learned significantly more about their chart than those who were taught the GS chart. Thus our overall conclusion from these two studies is that, in Lesotho, the RTH would be a more appropriate national chart than the GS. Nevertheless, it would be useful to replicate these results elsewhere in Africa where literacy of mothers and health workers is lower and more typical of much of Sub-saharan Africa. It would also be interesting to re-assess health workers' ability to use and interpret the two charts after use in growth monitoring activities.

We believe that the use of information from applied research, such as this, is fostered by the involvement of the national decision makers at all stages of the research process. In Lesotho, the decision was made to use a RTH-type chart on a nationwide basis, as recommended by our study. □

Acknowledgments

This research was funded by the Joint Program between UNICEF and Cornell Nutritional Surveillance Program, Cooperative Agreement # AID DSAN CA-0240 between USAID and Cornell University. Additional funding was provided by UNICEF. The authors wish to thank: Victoria J. Quinn from the Joint Program for her crucial work in the initiation and implementation of this research; John Haaga formerly from CNSP, now at the Rand Corporation, for writing the first research proposal; Martin Mogwanja, Assistant UNICEF Representative for Lesotho, for his remarkable efficiency and his continued support throughout the field work and at all stages of the research.

*The only difference was that for the RTH chart, some recommendations were made for children with constant weight (Appendix II). For the GS chart this was not possible because constant weight cannot be observed directly on the chart.

APPENDIX IIA— Guidelines for Action Based on the Interpretation of Growth Patterns Plotted on the Road-To-Health (RTH) or the Growth Surveillance (GS) Chart

Part 1. *For Children Re-attending the Clinic*

	Age 0–24 months		Age ≥25 months		
Direction of Growth	Gaining Weight	Constant/ Losing Weight	Gaining Weight	Constant Weight (only for RTH[a])	Losing Weight
Position of Dot					
A) Above 80%	• Regular plan of action[b] • Praise/ encourage	• Refer to nursing sister	• Praise/ encourage	• Regular plan of action (if constant weight for 3 months: refer to nursing sister	• Refer to nursing sister
B) Below 80%	• Regular plan of action • Home visit	• Refer to nursing sister • Home visit	• Encourage • Follow-up monthly	• Regular plan of action (if constant weight for 3 months: refer to nursing sister	• Refer to nursing sister

Part 2. *For New or Irregular Attenders*

	Age 0–24 months	Age ≥25 months
Position of Dot		
A) Above 80%	• Use "thinness chart"[c]	• Encourage monthly visits
B) Below 80%	• Use "thinness chart"	• Use "thinness chart"

Results of "Thinness Chart"

Green	Yellow	Red
• Praise/encourage • Encourage monthly attendance	• Refer to nursing sister	• Refer to nursing sister (very critical in children <24 months)

[a] On the GS chart, constant weight is not detected until the child's % weight-for-height (WTHT) drops. In this case, constant weight is detected on the GS chart by a downward slope, similar to the effect of a weight loss.

[b] See Appendix IIB.

[c] The "thinness chart" is a weight-for-height wall chart.[11] The interpretation of the color code is:
Green: WTHT between 70% and 80% of the NCHS standards
Yellow: WTHT between 80% and 90% of the NCHS standards
Red: WTHT between 90% and 110% of the NCHS standards.

APPENDIX IIB

Description of the Regular Plan of Action

REGULAR PLAN OF ACTION

1. Inform mother about her own child's growth (as seen on the growth chart). This should be done with all mothers.
2. Briefly interview mothers about their feeding practices. (Consider each age group: 0–3 months; 4–9 months; 9–12 months; over 1 year).
3. Give advice to mothers concerning specific feeding practices for each age group (taking mothers' reported practices into consideration). Suggested advice for each age group:

0–3 months	*4–9 months*
• Breastfeeding • Introduce liquids	• Breastfeeding • Introduce soft foods: cereals, fruits, vegetables, mashed/ pureed eggs
9–12 months	*>12 months*
• Breastfeeding • Continue soft foods • Introduce solids • Start meat/fish/ chicken/peas/ beans • Give frequent meals (>4/day)	• Breastfeeding • Adult foods: 3 food groups • Frequent meals (>4/day)

Evaluating AIDS Education Efforts

Preventing AIDS: A Guide to Effective Education for the Prevention of HIV Infection

By Nicholas Freudenberg, DrPH
236 pages, softcover, 1989

Preventing Aids sythesizes the collective experience of more than 130 AIDS educators nationwide and builds on case histories of AIDS education efforts, reviewing specific strategies used to contain the disease and providing a framework for decisions about future AIDS education activities.

Preventing AIDS will help you understand the social and political forces affecting AIDS educators. You'll also get practical advice on assessing a population's needs, developing educational materials, building coalitions, evaluating program effectiveness, and meeting the challenges of working with such specific populations as gay and bisexual males, IV drug users, youth, women, and the homeless.

An essential resource for health educators and administrators, nurses, teachers, activists, health department workers—anyone interested in AIDS education.

Evaluating Needle Exchange: Do Distributed Needles Come Back?

Joseph Guydish, PhD, MPH, George Clark, Delia Garcia, Moher Downing, Patricia Case, and James L. Sorensen, PhD

ABSTRACT

We employed capture-recapture methods as a strategy for evaluating needle exchange. Needles distributed by the exchange at two time periods were marked with color coded bands indicating the date and site of distribution. Half of the marked needles (2,068/4,239) returned within two weeks of distribution, and 61 percent (2,593/4,239) returned during the study period. The rate of return for stationary exchange sites (63 percent) was greater than that for roving/mobile sites (51 percent; $\chi^2 = 28.6$, p < .001). Of all needles returned, 87 percent (2,248/2,593) returned to the site of original distribution. (*Am J Public Health* 1991;81:617–619)

Introduction

Needle exchange programs can potentially slow the spread of the human immunodeficiency virus (HIV) among injection drug users (IDUs), their sexual partners, and their children. Needle exchange is controversial, however, in that it contradicts traditional drug treatment philosophy and removes at least one barrier to drug use. Reports from programs abroad suggest that needle exchange does not increase drug use or needle use, or encourage individuals to begin using nedles.[1–5] Whether these programs slow the spread of HIV remains unanswered. United States needle exchange programs now operate in several urban areas,[6–8] and there is a pressing need for evaluation. Strategies that do not rely on self-report can assist efforts to determine program effects.

One question is whether distributed needles return to the exchange. In the ideal program 100 percent of needles distributed would be returned in a short time, implying consistent use of new needles and a low likelihood of needle sharing in the exchange population. We employed capture-recapture methods to determine what proportion of distributed needles return to the exchange, how quickly needles return, and whether distributed needles travel between exchange sites.

The San Francisco exchange program (Prevention Point) trades needles on a 1:1 basis during regular hours on one night each week, and any patron may exchange up to 10 needles. There are two "roving" teams which travel on foot over a prescribed route, and two stationary teams. Together these sites exchanged an average of 2,806 needles per week during the study period.

Methods

Needles were identified for study purposes ("captured") with colored bands painted onto the barrel of each syringe. The color indicated both the site and date of distribution. Marked needles were distributed on two occasions. At Time 1, all needles distributed at Stationary Site A (n = 1,200) and Roving Site A (n = 204) were marked. At Time 2, nine weeks after the first distribution, marked needles were distributed at Stationary Site A (n = 1,300), Stationary Site B (n = 1,137), Roving Site A (n = 249), and Roving Site B (n = 149). These needles, marked with four colors different from those used at Time 1, comprised 95 percent (2,835/2,978) of all needles distributed at Time 2. After each distribution, all needles returned to any exchange site were inspected for a nine-week period, and banded needles (those "recaptured") were recorded.

This method is observational and unobtrusive. Exchange patrons were not interviewed, and no attempt was made to determine whether the original recipient of marked needles was also the person who returned them. Only needles collected by the exchange program were monitored, so no data are available concerning marked needles that did not return to the program. Prevention Point had distributed marked needles in conjunction

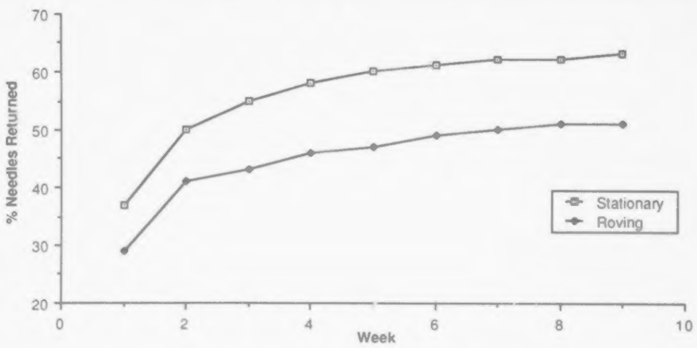
TABLE 1—Rate of Return for Banded Needles, Collapsed across Time of Distribution and Site

Week of Return	Needles Returned N = 4,239* (%)
1	1500 (35.4**)
2	568 (13.4)
3	195 (4.6)
4	129 (3.0)
5	83 (2.0)
6	37 (0.9)
7	30 (0.7)
8	34 (0.8)
9	17 (0.4)
Totals	2593 (61.2)

*Total number of banded needles distributed.

**Percentages rounded to one decimal place.



Proportion returned for Stationary Sites is 62.8% (2284/3637), and for Roving Sites, 51.3% (309/602). $X^2 = 28.6$, $p < .001$

FIGURE 1—Cumulative Rate of Return by Type of Exchange Site, Collapsed across Time Periods

with a previous study,[6] so that many exchange patrons were accustomed to receiving marked needles. In the present study, patrons who asked about the markings were told that we wanted to learn how long distributed needles remained on the street.

Results

Results are presented for Time 1 and Time 2 combined, since the proportion of needles returned (60 percent and 62 percent, respectively) and the general pattern of return were the same. The rate of return was inversely related to time since distribution, with the greatest return occurring in the first five weeks (Table 1).

For the stationary site evaluated at both time periods, there was no difference in rate of return across time (63 percent vs 62.9 percent). For the roving site, the rate of return was greater at Time 2 than at Time 1 (58.2 percent vs 43.1 percent; $\chi^2 = 10.2$, $p < .01$). At Time 2 there were no differences in rate of return for the two stationary sites (62.9 percent vs 62.4 percent), or the two roving sites (58.2 percent vs 51 percent). To evaluate differences in return rate by type of site, we collapsed data across time for stationary and roving sites (Figure 1).

Last, we evaluated how often needles returned to the site where they were distributed. Of the banded needles returned, 87 percent (2,248/2,593) were returned to the site of original distribution. For stationary exchanges the proportion of needles returning to the home site ranged from 88 percent to 94 percent. The proportion returning home to Roving Site A was lower (74 percent). Unexpectedly, only 12 percent (9/76) of returning Roving Site B needles came back to the home site, and 82 percent returned to Stationary Site B located in the same neighborhood.

Discussion

For both Time 1 and Time 2, nearly 50 percent of distributed needles returned within two weeks. This finding suggests some stability in the exchange population, and that many patrons use the exchange repeatedly. The difference observed for rate of return between stationary and roving sites suggests that these models, in San Francisco, may serve different IDU populations. Roving teams were designed to reach homeless IDUs who are more transient and whose needles are frequently lost or stolen. To the degree that roving teams reach this population, a lower rate of return would be expected. The finding that needles distributed by Roving Site B frequently returned to Stationary Site B indicates that these sites serve an overlapping population.

The application of nonself-report methods is vital in adequately evaluating the effects of US needle exchange programs. While such methods cannot replace self-report strategies, they can provide independent verification of self-report data. The capture-recapture method indicates the stability of the exchange population, the frequency with which patrons use the exchange service, and the degree to which different exchange sites serve unique populations. ☐

Acknowledgments

The authors gratefully acknowledge the assistance of members of the volunteer community based San Francisco needle exchange, Prevention Point, and the needle exchange patrons. George Chu, PhD, made early conceptual contributions to the project, and Norman Hearst, MD, contributed substantively to preparation of the manuscript.

Some of the data included in this manuscript were presented at the VI International Conference of AIDS, San Francisco, June 1990 (Abstract S.C.762)

Targeted HIV Screening at a Los Angeles Prenatal/Family Planning Health Center

Laura J. Fehrs, MD, Deirdre Hill, MPH, Peter R. Kerndt, MD, Thanne P. Rose, PhD, and Carol Henneman, MD

ABSTRACT

In 1988, the Los Angeles County Health Department conducted a blinded human immunodeficiency virus (HIV) seroprevalence study at a public prenatal (PN) and family planning (FP) center serving mostly Hispanic women in order to determine seroprevalence and to evaluate the center's targeted HIV screening program. Four women (0.13 percent) tested positive (3/1801 PN and 1/1167 FP). Three reported no risk factors; one reported a history of syphilis since 1978. Voluntary HIV testing was selectively offered to women who reported risk factors for HIV infection. Only 14 percent (96/685) of clients offered testing chose to do it: 28 percent (14/50) of clients classified as being at highest risk of infection, and 27 percent (16/59) of women who judged themselves to have some chance of being exposed to HIV. None of the four women who tested positive by blinded testing chose testing. While few women at this center were infected with HIV, higher risk women were not persuaded to be tested through a targeted screening program. Blinded HIV seroprevalence studies provide a tool for both tracking infection in a population and evaluating screening programs. (*Am J Public Health* 1991;81:619–622)

Introduction

Women of childbearing age in the United States are at risk for human immunodeficiency virus (HIV) infection although their risk varies by locality, risk group, and race.[1–14] In 1987, the US Public Health Service (PHS) recommended that women with identifiable risks for HIV infection be routinely counseled and tested for HIV antibody.[15] Strategies for providing women of childbearing age with HIV counseling and testing include: 1) routine or universal screening, with informed consent, of women attending women's health clinics, such as prenatal (PN) or family planning (FP) clinics and 2) selective targeting of women identified as having risk factors for HIV infection. In the latter approach, risk factors for HIV infection are assessed during a counseling session and those patients reporting risk factors are offered voluntary testing. In areas with high rates of HIV seropositivity among women, this approach has not been shown to be effective in identifying most seropositive women.[3,4,8,10,16] Fewer data exist for areas with low or unknown rates of seropositivity among women, such as Los Angeles.

In 1988, the Los Angeles County Department of Health Services participated in the PHS Family of Surveys[17] and initiated a blinded HIV seroprevalence study at a large inner-city public health center which used a targeted approach for HIV counseling and testing in its PN and FP clinics. Results of blinded HIV testing were used to evaluate the extent to which the HIV counseling and testing program reached women who were either at risk for HIV infection or already infected.

Methods

Consecutive sera remaining after routine syphilis testing during initial or annual visits of all women attending the PN clinic from March through September, and the FP clinic from March through November, 1988 (3,000 total) were blinded by the removal of personal identifiers and then tested for HIV antibody by a licensed enzyme linked immunosorbent assay (ELISA) kit. Repeatedly reactive specimens were confirmed with immunofluorescent antibody (IFA) (Laboratory Services Branch, California State Department of Health Services) and Western blot.

The clinics used a targeted HIV counseling and testing program. All patients were counseled by trained bilingual interviewers about risk factors for HIV infection and the availability of HIV testing. The interviewers used a questionnaire

Dr. Rose was with the AIDS Epidemiology Office at the time of the study. She is currently with the Academy of Pediatrics in Chicago, Ill. This paper, submitted to the Journal May 22, 1990, was revised and accepted for publication November 20, 1990.

TABLE 1—Definition of Risk for HIV Infection Used by Clinic Staff and by Investigators, and Prevalence of Risk Behaviors, Los Angeles, 1987–88

	Risk behaviors (+) for which clinic staff offered voluntary testing	Risk behaviors (+) for which women were classified as "high risk" by investigators	Women with risk behavior No. (%)
Intravenous (IV) Drug Use since 1978	+	+	8 (0.3)
Sex since 1978 with an IV drug user, bisexual man, or person with AIDS or HIV infection	+	+	47 (1.6)
Receipt of money or drugs for sex in the last year	+	+	12 (0.4)
Transfusion from 1978 through 1985	+		107 (3.6)
Sex since 1978 with a prison inmate	+		172 (5.7)
Sex since 1978 with a man with hemophilia	+		0 (0)
Sex since 1978 with a man from Haiti or Central Africa	+		6 (0.2)
History of hepatitis	+		48 (1.6)
History of a sexually transmitted disease since 1978	+		38 (1.3)
History of more than one sex partner in the last year	+		165 (5.5)
History of sexual assault	+		60 (2.0)

TABLE 2—Results of HIV Antibody Seroprevalence Study, Los Angeles, 1987–88

		HIV Antibody Seroprevalence		
	% of All Patients	No. HIV Positive	Total No. Tested	% Positive
Clinic Type				
Prenatal	60.0	3	1801	0.17
Family Planning	38.9	1	1167	0.09
Unknown	1.1	0	32	0
Risk For Infection				
No Risk Behaviors Reported	77.0	3	2311	0.13
"At Risk" (Any risk behaviors reported)	23.0	1	689	0.15
"High risk"*	1.7	0	50	0
Self-Assessed Risk of ≥ 1 in 100 chance**	2.0	0	60	0

*Subset of "At Risk" group; these two groups were not mutually exclusive. See Table 1 for definitions.

**Self-assessment of risk of exposure was determined by interviewer asking patient "How likely do you think it is that you have been exposed to someone infected with the AIDS virus in such a way that you could be infected?" Patients were given the choice of answering "Very unlikely (less than 1 in 100 chance)", "Unlikely (1 in 10 chance)", "Uncertain (50-50 chance)", or "Certain (sure that you have been exposed to someone infected with the AIDS virus)."

as a guide to counseling and as a record of risk behavior information. To identify all women possibly at risk, the clinic chose to use a broad range of behaviors in its definition of risk (Table 1) and patients were also asked to assess their own risk (Table 2). Voluntary HIV testing was recommended and immediately offered to all women who requested testing and to those reporting any of the behaviors defined by the clinic to indicate possible risk.

The targeted HIV counseling and testing program was evaluated by using a unique study number to link the results of blinded seroprevalence testing to questionnaire information. Women were classified by their answers as being "at risk," "at high risk," or "not at risk." The "at risk" group was composed of those women who reported any of the broad range of risk behaviors which the clinic considered to place women at some risk of infection (the group that was offered HIV testing). A subset of "at risk" women, "high-risk" women, was defined by investigators to be at particularly high risk for HIV infection, using objective criteria (Table 1).

Confidence limits for proportions were calculated using the method published by Fleiss.[18]

Results

A total of 1,801 consecutive specimens from the PN clinic, 1,167 consecutive specimens from the FP clinic, and 32 specimens for which clinic type was not known were tested for HIV antibody (Table 2). Of the patients for whom race was known (2,955), 87.3 percent (2,579) were Hispanic, 9.6 percent (285) White, 2.4 percent (71) Black, 0.5 percent (15) Asian, and 0.2 percent (5/2,955) other race. The median reported length of residence in the US was five years. The median age was 25 years with a range of 12–46 years; age was unknown for 29 women.

Four of the 3,000 specimens (0.13 percent, 95 percent confidence interval (CI) = 0.04, 0.37) were repeatedly reactive by ELISA and positive by IFA and Western Blot; three were from the PN clinic (0.17 percent, 95% CI = 0.04, 0.55), and one was from the FP clinic (0.09 percent, 95% CI = 0.00, 0.55) (Table 2). These positive specimens were from one White and three Hispanic patients, all of whom were in the 20–24 age group. The length of time that these patients reported residing in the US ranged from two to 12 years.

None of the four seropositive women chose voluntary HIV testing (Table 3). Only one of the four reported any risk factor for infection—a history of syphilis since 1978 (Table 2). Because this finding was of concern, we further investigated the center's testing strategy by determining the rate of acceptance of testing among those reporting risk behaviors.

While 23 percent of women reported one or more risk behaviors (were considered "at risk" by clinic staff) and 1.7 percent met the criteria for classification as "high risk," only 2.0 percent judged themselves to have more than a one in 100 chance of being exposed to HIV infection (Table 2). A high proportion of women who were "at risk" (92 percent) or even "high risk" (66 percent) assessed their own risk for being exposed to HIV infection to be "very unlikely" (less than a one in 100 chance) (Table 4). All four of the

TABLE 3—Acceptance of Voluntary HIV Testing, by Risk Group

Risk Group	No. Accepted Voluntary HIV Testing	Total No. in Group*	% Accepted Voluntary Testing
Reported Risk Behaviors			
"At Risk" (Any risk behaviors reported)	96	685	14.0
"High risk"	14	50	28.0
Self-Assessed Risk	16	59	27.1
Tested Positive in HIV Seroprevalence Study	0	4	0
Tested Negative in HIV Seroprevalence Study	110	2985	3.7

*Persons for whom acceptance of testing was not known were excluded from analysis

seropositive women also assessed their own risk as being "very unlikely."

Not only did the four seropositive women refuse HIV testing, but only 14.0 percent of women offered testing because of a history of risk behaviors ("at risk" group) consented (Table 3). Among the women who were classified as being "high risk" and among the women who judged their chance of exposure to be greater than one in 100, only 28.0 percent and 27.1 percent, respectively, selected voluntary testing.

Comments

The prevalence of HIV antibody among prenatal and family planning patients attending this inner-city, mostly Hispanic, public health center in Los Angeles was low—0.13 percent (95% CI = 0.04, 0.37). The rate found in this study is consistent with the low prevalence of antibody reported from parturients (0.04 percent),[19] newborn screening (0.10 percent),[20] and FP clinics (0.1 percent, D. Hill, unpublished data) in Los Angeles County. Since the population in this study was predominantly Hispanic and immigrant, it should not be considered representative of all clinics with a high proportion of minority clients. But, as one of six large comprehensive public health centers in Los Angeles, it is an important site for monitoring HIV infection.

While the seroprevalence found at this center was reassuringly low for an urban area with a high incidence of AIDS, it is of concern that the program of targeted HIV screening did not identify the seropositive women in this study. Three of these four women reported no risk factors for infection. The rates of reporting of risk behaviors and acceptance of testing in this population may have been affected by cultural factors and/or lack of knowledge of risk behaviors of partners. Some women may have been tested already for HIV infection for immigration or other purposes. Acceptance of testing may have been affected in unknown ways by the counseling process; however, in this regard, the clinic is probably typical of urban, high-volume clinics.

Our data suggest that a strategy of selectively offering HIV voluntary testing only to those women who report risk factors for infection may result in a low rate of acceptance and may miss seropositive women. Similar data from several studies led the US Public Health Service's Immunization Practices Advisory Committee to recommend the universal screening of PN patients for hepatitis B.[21–26] Universal screening for HIV of all women pregnant or contemplating pregnancy has been recommended[1–4,16,27,28] because it identifies a high proportion of infected women; these women can be referred early to medical prophylaxis and treatment; and it results in the early identification and treatment of children born to HIV-infected mothers. Universal screening, with informed consent, has been conducted at some Los Angeles prenatal clinics since 1988.

Despite the benefits of universal screening, targeted screening may be used in localities with a low prevalence of HIV or without resources for adding large scale HIV testing and counseling to routine clinical practice. Efforts to identify seropositive women compete for limited resources with HIV prevention and other public health programs. In a 1988–89 random survey of urban hospitals, most did not offer HIV testing routinely to pregnant women.[28]

Those who design voluntary HIV screening programs for women should consider: local seroprevalence; available resources vs demand for testing and other services; local characteristics of women at risk for infection; strategies that result in high levels of acceptance of testing among women at risk; and strategies that provide counseling to seronegative women and effect behavioral changes that will prevent the future transmission of HIV.

The variety of strategies for screening women of childbearing age should be evaluated locally and over time. Blinded HIV seroprevalence studies provide valuable data about voluntary screening programs. In addition, they supplement acquired immunodeficiency syndrome case

HIV-1 Prevalence in Selected Tijuana Sub-populations

Fernando Güereña-Burgueño, MD, Abram S. Benenson, MD, and Jaime Sepúlveda-Amor, MD

ABSTRACT

To assess the prevalence of HIV-1 (human immunodeficiency virus) infection among high-risk populations in Tijuana, Mexico, HIV-1 antibody status was determined and information on risk behavior was obtained from 1,069 individuals in three high-risk groups. The prevalence of HIV-1 among 415 prostitutes was 0.5 percent; 410 prisoners, 1.2 percent; 233 homosexual/bisexual men, 11.6 percent; and 106 intravenous drug abusers, 1.9 percent. The potential for spread of HIV-1 exists in Tijuana despite the current relatively low seroprevalence of HIV-1. (*Am J Public Health* 1991;81:623–625)

Introduction

By December 31, 1989, 3,512 AIDS (acquired immunodeficiency syndrome) cases have been reported to the Mexican Ministry of Health.[1] Projections made by the Mexican National Committee for AIDS Prevention (CONASIDA) suggest that the cumulative AIDS case total could exceed 75,000 by the end of 1991.[2] The majority of the 71 AIDS cases in the state of Baja California[2] have been reported by the city of Tijuana, geographically contiguous to San Diego, California. This border area is the busiest port of entry to the United States, with approximately 36 million legal entries of alien and US citizens, and more than 500,000 illegal aliens deported in 1987.

This study presents the results of a cross-sectional epidemiologic and serological survey designed to determine the prevalence of infection with the human immunodeficiency virus type 1 (HIV-1) among "high-risk" populations in Tijuana. The project was approved by the Committee on Protection of Human Subjects of the San Diego State University.

Methods

Sample sizes were selected to provide less than 3 percent margin of error ($\alpha = .05$ and $1\text{-}\beta = .80$) (4). From 1,967 prisoners in the Tijuana State Penitentiary, 410 were recruited by selecting every fifth prisoner listed in the prison records. From 2,000 active prostitutes registered at the Municipal Medical Services Clinic, 415 were sequentially included in the study. A convenience sample of 233 homosexual/bisexual men was recruited in diverse homosexual gathering sites. From 1,000 intravenous drug abusers with files at the Juvenile-Integration Center detoxification clinic at Tijuana, a sample size of 341 was included in the study by selecting every third individual listed in the clinic records.

Participation was voluntary and anonymous. Each subject was individually counseled prior to testing. Sociodemographic and risk factor information was obtained and a blood sample was drawn. Test results with post-test counseling were offered to the participants.

Antibodies against HIV-1 were determined with licensed enzyme-immunoassay (EIA) kits.[5] Those repeatedly reactive were then confirmed by the indirect immunofluorescent antibody assay (IFA)[6,7] or by the Western blot technique.[8]

Descriptive statistics and odds ratios were calculated and 95 percent confidence intervals estimated with Cornfield's method.[9]

Results

Questionnaires were completed and blood samples obtained from 1,069 individuals. The refusal rate was 2 percent in the prisoner and prostitute groups and 25 percent to 30 percent in the group of homosexual/bisexual men. Only 11 of the 341 drug abusers in the files of the detoxification clinic could be located. However, 95 individuals in the other three groups admitted intravenous drug abuse (IVDA).

A total of 34 individuals tested positive for HIV-1. The prevalence rates by study group, sex, and history of IVDA are shown in Table 1.

Seropositive homosexual/bisexual men exhibited high-risk behavior patterns (Table 2); a history of receptive anal sex showed the strongest relation to HIV-1 infection. For vaginal sex, 36 percent (139/383) of prostitutes reported using condoms "usually" or "always." Of female prostitutes and female prisoners participating in the study, 12.3 percent (46/383) and 5.9 percent (2/34), respectively, reported anal sex.

TABLE 2—Behavior Patterns among Homosexual/Bisexual Men by HIV-1 Antibody Status, Tijuana HIV-1 Seroprevalence Study, June–October 1988

	Seropositive		Seronegative			
Behavior	N	(%)	N	(%)	OR*	95% CI**
History of drug abuse	16/27	(59.3)	87/206	(42.3)	2.0	0.82, 4.9
History of sexually transmitted disease	15/27	(55.6)	83/206	(40.3)	1.9	0.77, 4.5
History of receptive anal sex	21/27	(77.8)	113/206	(54.9)	2.9	1.0, 8.4
History of prostitution	11/27	(40.7)	67/206	(35.5)	1.4	0.58, 3.5
History of sex in the US	12/27	(44.4)	60/206	(29.1)	2.0	0.80, 4.7
Usually or always using condoms	5/27	(18.5)	55/206	(26.7)	0.62	0.20, 1.9

*Odds ratio
**Comfield's 95% confidence limits

Within the penitentiary, 30 percent (117/410) of the prisoners reported current use of illegal drugs, 47 percent of the current users reported using IV drugs. Regular use of condoms was reported by only 4.2 percent (17/403) of the sexually active prisoners.

Discussion

This study is the largest survey reported of HIV-1 seroprevalence among potential high-risk populations in Tijuana. Nevertheless, it was impossible to reach and make precise estimates of the number and location of the homosexual/bisexual men; self-selection may have biased the seroprevalence estimated in this group. The main reason of failure to find the drug abusers selected from the clinic, was that most of them were residents of the neighboring state of California, who came to Tijuana for treatment. The almost complete lack of refusal among the prisoners and prostitutes groups actually eliminates concern of selection bias. However, bias could have been introduced when obtaining information by questionnaire regarding sensitive issues, such as sexual behavior and drug abuse.

Plausible hypotheses can be offered to explain the relatively low seroprevalence of HIV-1 infection found in this study. First, the number of partners claimed by the homosexual group is lower than that reported in high incidence places.[10–12] Second, the availability in pharmacies of sterile syringes without the requirement of a medical prescription may result in less sharing of used needles among drug abusers. However, the 1.9 percent prevalence of HIV-1 positivity in this group was similar to that estimated in various studies conducted in the Southern California area, ranging from 0 percent to 7 percent.[13] Third, the low rate among prostitutes may be attributed to the increased health consciousness of this group with monthly medical contact. Fourth, the legal weekly permission for the prisoners to receive conjugal visits by spouses or prostitutes might have lessened the possibility of widespread unprotected homosexual activity among the prisoners; however, 5 percent (19/376) of the prisoners reported history of homosexual contact during the last year. The lower availability of sterile syringes in this site and the low use of condoms indicate a serious potential of spread of HIV-1 should the virus be brought into the prisoner group.

Experience has shown that reduction in HIV-1 transmission, as well as other sexually transmitted diseases, is possible when reduction of high-risk sexual practices is induced by means of preventive intervention.[14–16] Logistic support in the implementation of preventive efforts needs to be permanently offered to nongovernmental AIDS organizations by the health authorities and coordinated and complementary action by the two countries must follow. ☐

HIV Infection in an Ethiopian Prison

Yohannes Kebede, MD, MPH, Joyce Pickering, MD, Jane C. McDonald, MD, Kay Wotton, MD, MPH, and Debrework Zewde, PhD

ABSTRACT

HIV-1 antibody was detected in 6.0 percent of prisoners in an Ethiopian prison. HIV-1 seropositivity was strongly associated with positive VDRL status (RR = 3.7) and recent admission to prison (RR = 3.5). Seropositive prisoners were more likely to have prostitute contacts. No correlation was found between seropositivity and number of sexual contacts, long-term sex partners, or dental extractions. HIV-1 infection in this area may be of recent origin and the high prevalence may reflect rates in the surrounding community. (*Am J Public Health* 1991;81:625–627)

Introduction

Infection with human immunodeficiency virus (HIV-1) in Africa has increased rapidly. By 1988, 11,753 cases had been reported from 45 countries.[1,2] In Ethiopia, 285 AIDS (acquired immunodeficiency syndrome) cases have been reported to the National AIDS Prevention and Control Unit, by January 1990,[3] the majority (70.4 percent) from Addis Ababa.

This study was conducted in the major prison in Dire Dawa to assess the rate of HIV-1 seropositivity and associated factors. Dire Dawa is on the main communication and trade route linking Addis Ababa to the Red Sea ports of Assab and Djibouti. People in the area have high mobility and contact with neighboring regions and countries. Information obtained will lead to more relevant approaches to health prevention practices in prisons in Ethiopia and to increased awareness of the extent of HIV-1 infection in this region.

Methods

Four hundred fifty consenting prisoners from Dire Dawa District prison, present in November 1988, were enrolled. An oral closed-ended questionnaire was pretested and then administered after standardized translation into Oromingna, Somaligna, and Amharic.

Characteristics including age, sex, education, marital status, and time in prison were determined. Aspects of sexual behavior were obtained during confidential interviews.

All participants had blood samples drawn for HIV-1 and VDRL status. HIV-1 testing was done in the National

Pickering, McDonald, and Wotton are affiliated with the Department of Epidemiology and Biostatistics, McGill University, and with the Department of Community Medicine, Addis Ababa University; Dr. Zewde is with the AIDS Laboratory, National Research Institute of Health, Addis Ababa, Ethiopia. Drs. Pickering, McDonald, and Wotton are fellows of the Royal College of Physicians (Canada). This manuscript, received June 19, 1990, was revised and accepted for publication January 23, 1991.

Research Institute of Health (NRIH) in Addis Ababa using the Wellcozyme competitive enzyme linked immunosorbent assay (ELISA) (Wellcozyme anti-HTLV-III, Wellcome Diagnostics, Dartford, UK). All repeatedly reactive specimens were analyzed by Western Blot (Bio-Rad Novapath Immunoblot Assay) and considered positive if bands corresponding to at least one core protein and one envelope protein were visualized.

Syphilis serology was performed using the Venereal Disease Research Lab (VDRL) test.

Associations between HIV-1 seropositivity and sociodemographic factors and risk behaviors were examined using cross-tabulation, chi-square tests, t-test, and odds ratios with their 95 percent confidence limits. Data analysis was carried out using the SPSS statistical program.

Health education was provided to all respondents at the time of the interview. Confidential counseling to all seropositive and seronegative prisoners was offered when results were known. Those with positive VDRL tests were offered Benzathine penicillin G. with all receiving treatment.

Results

During the period November 12–23, 1988, 450 prisoners were enrolled. Of these, 27 (6.0 percent) had positive HIV-1 serology; 141 (31.6 percent) had a positive VDRL titer.

Table 1 compares relevant demographic characteristics in HIV-positive and HIV-negative prisoners. Older prisoners were 2.5 times more likely to be HIV seropositive. There was no significant association between HIV-1 seropositivity and education status, gender, or marital status. A shorter stay (< three months) was significantly associated with HIV-1 seropositivity.

Table 2 compares selected sexual behaviors. Prisoners with prostitute contact before prison were 2.5 times more likely to be HIV-1 seropositive than those prisoners who denied such contact although this did not reach statistical significance. HIV seropositivity was not significantly associated with either the number of long-term sex partners or the frequency of sexual contacts before prison. None of the prisoners reported homosexuality.

Lack of circumcision, and number of injections or dental extractions did not correlate with seropositivity (Table 3).

TABLE 4—VDRL Status and HIV Infection

	HIV-positive n (%)	HIV-negative n (%)	Relative Risk (95% Confidence Interval)
VDRL Status			
Negative	10 (3.2)	299 (96.8)	
Positive*	17 (12.0)	124 (88.0)	3.7 (1.75,7.93)

*significant variable ($p < 0.001$)

The association between positive VDRL status and HIV-1 positivity was significant (Table 4).

To determine whether age was a confounder in the association between HIV positivity and other variables, chi square analyses were performed. The only significant association with age was time in prison such that young prisoners were more likely to have short stays. Because both older age and shorter stay in prison were associated with higher seropositivity rates, the effect of age on the bivariate analysis is to underestimate the shorter prison stay and higher seropositivity association.

Discussion

The seropositive prisoners in this study represent a prevalence of 6.0 percent. Among high-risk groups such as Ethiopian prostitutes, rates from 16 percent to 60 percent have been reported.[4]

Higher rates of HIV infection have been shown in prisoners than the general population. Seropositivity rates of 11 percent, 16.8 percent, and 26 percent have been reported from Switzerland, Italy, and Spain, respectively.[5] The spread of HIV infection in closed institutions is a major public health concern. An estimated 21,000 to 42,000 prisoners were infected with HIV in American State prisons in 1986 with 420 diagnosed cases of AIDS.[6-8] Although no studies have looked at the problem in African prisons, a similar situation is considered likely to exist.

The fact that short duration of stay was associated with seropositivity suggests that HIV was recently introduced into the town. Dire Dawa is on the main truck and trade route between Addis Ababa and the Red Sea, and infection could have been introduced from either direction.

Positive VDRL status was strongly associated with HIV positivity, as has been reported from Nairobi.[11] Men with HIV infection may be more susceptible to syphilis, or syphilis could change the susceptibility of the host by providing a portal of entry for the virus through a genital ulcer. Positive VDRL status may indicate greater exposure to sexually transmitted diseases including HIV[9,10] Genital ulcers, either by history or by examination, were significantly associated with HIV seropositivity in Nairobi.[11] Studies in homosexual populations have confirmed the association of genital ulcers and HIV transmission.[12]

Frequent use of prostitutes has been shown to be associated with HIV seropositivity.[11,13] In our study, a trend was apparent but not significant, possibly because of the small number of seropositive prisoners. Nevertheless, the trend, is suggestive.

A history of injections was not associated with seropositivity in this study. Results from studies in Zaire have been equivocal.[14,15] However, the continuing use of unsterilized needles in many African countries may potentially facilitate HIV transmission.

Immunizations and dental extractions were not associated with HIV seropositivity although the number of positive respondents in this area was small.

In summary, a prevalence rate of 6.0 percent was found in this prison population. The general HIV seroprevalence rate in Ethiopia is approximately 2 percent seropositivity in blood donors.[3] HIV infection appears to have been recently introduced into the area and this high rate is evidence of rapid spread in this group. Seropositivity was significantly associated with positive VDRL status and seropositive men reported more frequent prostitute contacts.

Significant educational efforts are needed to prevent further spread of HIV infection into the surrounding community. ☐

Acknowledgments

This study was supported by a research grant from the International Development Research Center, Canada. Special thanks go to Drs. Francis Aboud, Charles Larson, and Gary Pekeles from the McGill-Ethiopia Community Health Project; the staff and prisoners of the Dire Dawa Prison; the Department of AIDS Control of the Ministry of Health of Ethiopia; and the team of the AIDS Laboratory of the National Research Institute of Health.

Comparison of AIDS Knowledge, Attitudes, and Behaviors among Incarcerated Adolescents and a Public School Sample in San Francisco

Ralph J. DiClemente, PhD, Mark M. Lanier, MS, Patricia F. Horan, PhD, and Mark Lodico, PhD

ABSTRACT

Data collected from incarcerated youth (n = 113) and a public school sample (n = 802) demonstrate that both adolescent groups have a high level of AIDS knowledge. Incarcerated youth are less aware of HIV risk-reduction behaviors and report markedly higher rates of HIV risk behaviors. Incarcerated youth are at substantially increased risk of HIV infection relative to their school-based counterparts and should be a primary target of HIV prevention programs. (*Am J Public Health* 1991; 81:628–630)

Introduction

Although studies have identified the prevalence of risk behaviors among incarcerated adolescents,[1-3] as well as their knowledge about acquired immunodeficiency syndrome (AIDS),[4] at present, there are no data available comparing knowledge, attitudes, and risk behaviors between this population and a referent adolescent population. In making such a comparison, it is important to control for geographic site given recent findings indicating geographic variation in adolescents' knowledge and attitudes about AIDS,[5] prevalence of HIV (human immunodeficiency virus)-related risk behaviors,[6,7] and HIV prevalence.[8]

The present study provides a comparison of knowledge, attitudes, and HIV-related risk behaviors between adolescents in a detention facility and those in public schools in San Francisco.

Methods

In February 1988, all students enrolled in family life education classes, a required course, in nine primary high schools in the San Francisco Unified School District were asked to participate in the Centers for Disease Control (CDC) surveillance survey of adolescents' knowledge, attitudes, and risk behaviors.[9] Students completed an anonymous self-report survey during a single class period. It provided demographic information and asked about knowledge of AIDS transmission and prevention, sexual behavior, and intravenous drug use. Adolescents incarcerated at an adolescent detention facility in San Francisco also completed the survey, following the same administration protocol used with the school-based sample.

The age, ethnicity, and gender distributions of the school and incarcerated samples, while representative, demonstrate substantial differences particularly with respect to ethnicity and gender. To control for potential differences attributable to demographic variables when comparing survey responses between the samples, multivariate logistic regression analysis[10] is used to adjust for age, gender, and race.

Results

Response rates for school and incarcerated adolescents were high, 96.7 percent and 91.1 percent, respectively. Demographic characteristics of the samples are described in Table 1.

School and incarcerated adolescents generally demonstrate a high level of AIDS knowledge, with few substantial differences (Table 2). Most of the incarcerated youth correctly identify sharing of intravenous drug needles (86 percent) and sexual intercourse (90 percent) as routes of HIV transmission compared with 89 and 90 percent, respectively, for their school-based peers.

Knowledge of risk-reduction strategies identified informational gaps among both school and incarcerated youth; although incarcerated youth were less knowledgeable. While 85 percent of school youth correctly identified condom use as a means of reducing the risk of HIV transmission, only three-fourths of the incarcerated youth did so. Further, only 62 percent and 56 percent of incarcerated youth recognized that, respectively, sexual abstinence and not having sexual partners who use IV (intravenous) drugs reduce the risk of HIV infection. Among the

Asian	5.5	55.9	50.4 (45.0, 55.8)
Other	8.3	6.6	1.7 (0, 7.1)

95% CL = 95% Confidence Limits

school-based sample, correct responses were 80 percent and 72 percent, respectively.

Attitudes about AIDS

Both samples strongly endorsed the need for AIDS education (Table 2). Marked differences were identified with respect to perceived risk of HIV infection, as 69.4 percent of incarcerated youth compared with 45.2 percent of the school-based sample perceived themselves susceptible to infection. Awareness of AIDS information resources or where to receive an antibody test was low, although incarcerated youth are more knowledgeable than their school-based peers.

Prevalence of Risk-Taking Behavior

Substantial differences were identified between the samples with respect to prevalence of HIV risk behaviors (Table 3). Almost all incarcerated youth report being sexually experienced compared with approximately 28 percent of the school sample. Most incarcerated youth (73 percent) report two or more sex partners within the past year compared with approximately 8 percent of the school sample. A large proportion of incarcerated youths initiate sex at an early age as approximately 52 and 26 percent of the incarcerated and school samples, respectively, report sexual onset at 12 years of age or younger. Condom use among both samples is inconsistent, although incarcerated youth report being less likely to be consistent condom users. Intravenous drug abuse is prevalent, especially among incarcerated youth, although roughly sim-

ilar proportions of intravenous drug users in each sample report sharing needles.

Discussion

Incarcerated adolescents compared with a school sample demonstrate similar levels of AIDS knowledge, although they are less likely to be knowledgeable of prevention strategies—especially the protective value of condoms. Incarcerated youth were more likely to be sexually active, they initiated sex at an earlier age, report more sexual partners, and a smaller proportion use condoms consistently. This combination of behaviors will greatly increase the risk of HIV infection in this population. Likewise, the higher prevalence of intravenous drug abuse among incarcerated youth will also increase their risk.

The findings indicate an urgent need to implement effective AIDS prevention programs for these high-risk youth. AIDS prevention programs specifically targeted for incarcerated youth will have to overcome particular barriers to behavior change, such as low motivation for self-protection and lack of self-esteem.[11] Without prompt intervention, the potential for rapid spread of HIV infection in this population and transmission to other adolescents and adult populations appears substantial. □

The Donation and Sale of Blood by Intravenous Drug Users

Dale D. Chitwood, PhD, J. Bryan Page, PhD, Mary Comerford, MSPH, James A. Inciardi, PhD, Clyde B. McCoy, PhD, Edward Trapido, ScD, and Shenghan Lai, PhD, MPH

ABSTRACT

In spite of efforts to dissuade intravenous drug users (IVDUs) from donating or selling blood, some continue to do so. As part of a longitudinal study, 915 IVDUs in South Florida were interviewed concerning their history of donation or sale of blood and tested for antibodies to HIV-1 and HTLV-I/II. Approximately 17 percent had either donated or sold blood during 1985 through 1988; most contributors (80.4 percent) sold to commercial blood services. IVDUs who had donated/sold blood were more likely to be male and not in drug treatment than were those who had not contributed blood. IVDUs not in treatment at the time of interview were more likely than IVDUs in treatment to have sold blood. Of those who had donated/sold blood since 1985, 19.6 percent subsequently tested positive for antibodies to HIV-1 and 5.7 percent were positive for antibodies to HTLV-I/II. Increased effort is required to screen prospective donors and sellers, particularly at commercial blood banks. (*Am J Public Health* 1991;81:631–633)

Introduction

Because HIV infectivity precedes antibody formation,[1,2] blood service organizations must rely on self-reported history and physical signs to exclude intravenous drug users (IVDUs) from donor pools. The exclusion of IVDUs is also important because they are at high risk for the human lymphotropic viruses (HTLV-I/II),[3,4] which can be transmitted through infected blood[5,6] but for which blood services do not routinely screen.

In spite of increased donor exclusion efforts, IVDUs continue to donate and sell blood.[7] Nelson and colleagues[8] studied the blood donation histories of a predominately Black cohort of IVDUs from the Baltimore metropolitan area and reported that 27.1 percent had donated or sold blood between 1978 and 1988. Data from other geographic areas have not been reported.

We studied a tri-ethnic cohort of IVDUs in Miami-Dade County, Florida, which has the highest number of cases of AIDS (acquired immunodeficiency syndrome) attributable to parenteral drug use in the Southeastern United States.[9] As part of this investigation, we assessed the seroprevalence of HIV-1 and HTLV-I/II among the study sample, compared IVDUs who donated/sold blood with those who did not, compared donors with sellers, and examined the association of drug treatment with the donation/sale of blood.

Methods

Between June 1987 and August 1988, 915 IVDUs in South Florida were enrolled in a longitudinal study to determine HIV-1 serostatus and associated risk behaviors (22.8 percent were HIV seropositive at baseline). Seven hundred and four participants were recruited from drug treatment facilities in South Florida (eight methadone maintenance clinics, three residential drug-free programs, and one residential detoxification facility). An additional 211 subjects not enrolled in a drug treatment program were recruited directly from the streets. All subjects had used a drug or drugs intravenously at some time since January 1, 1978. All participated on a voluntary basis, gave informed consent, were tested for HIV-1 serostatus, and received pre- and post-test counseling. As part of a structured questionnaire, participants answered questions concerning their most recent donation or sale of blood. All were assured these data would be kept fully confidential and would not be disclosed to anyone including treatment center staff. Participants were paid a fee after completion of venipuncture and interview.

All sera were tested for the presence of antibodies to HIV-1. Residual sera, available on 874 of the study participants, were tested subsequently for antibodies to HTLV-I/II. Because of cross-reactivity, the assay did not differentiate between antibodies to HTLV-I or HTLV-II.

Serum was determined to be positive for antibodies to HIV-1 after two positive ELISAs (enzyme-linked immunosorbent assay) determined with Abbott Enzyme Immunoassay and a confirmatory positive Western Blot following the Centers for Disease Control protocols using viral lysate from Hillcrest Biologicals. A radioimmune assay utilizing an in-house ^{125}I-ionated core protein (p24), purified from human virus, was the antigen for detecting antibody to HTLV-I/II. Serum samples were tested at dilutions of 1:10 and 1:100, which bracket the dilution levels of maximum sensitivity for sera of all titers. Sera were evaluated in terms of percent-bound counts using a high-titered reference se-

rum at 1:100 dilution as the 100 percent standard. Sera were scored as positive if the percent-bound counts were greater than 5 percent at the 1:100 dilution.

Logistic regression analysis was used to evaluate the possible association between demographic characteristics of IVDUs and their behavior regarding the donation or sale of blood since 1985.

Results

Of the 915 IVDUs interviewed, 153 (16.7 percent) reported that they had donated or sold blood since January 1, 1985; four out of five (80.4 percent) of these 153 IVDUs had sold blood. A total of 22.8 percent of the study population tested positive for HIV-1 (Table 1). Of the 153 IVDUs who had contributed blood, 19.6 percent tested positive for antibodies to HIV-1 at the time of interview.

Of the subjects who had donated or sold blood, 5.7 percent of those tested for HTLV-I/II were positive. Serostatus at the time they donated/sold their blood is unknown.

When IVDUs who had donated or sold blood were compared with IVDUs who had not done so in a logistic regression, males and IVDUs who were not in treatment were more likely to have donated/sold blood (Table 2). No differences were observed by ethnic or age group. The demographic characteristics of IVDUs who had donated and those who had sold blood were also compared (data not shown). Donors were differentiated from sellers only by treatment status. Of those in treatment who had sold/donated blood, 68.5 percent had sold; 98.8 percent of the IVDUs from the street had sold rather than donated.

Discussion

Although participation in the study was voluntary, results indicate that the donation and sale of blood by IVDUs is not restricted to the Northeastern United States, and that the sale of plasma or blood accounts for almost all IVDU involvement in the blood supply. The percentage of IVDUs in South Florida (16.7 percent) who donated or sold blood between 1985 and 1988 was virtually identical to the 15.0 percent reported by Nelson and colleagues[8] for a cohort of IVDUs in Baltimore. At least four out of five IVDUs from both Miami (80.4 percent) and Baltimore (88.1 percent) who contributed blood during that time period had sold blood or plasma at a commercial service rather than donated at a voluntary blood center.

Blood services utilize blood screening procedures to ensure that the supply is as safe as possible, but the elimination of high-risk donors remains an unfinished task in the overall plan to protect the blood supply. Since the initiation of blood screening for HIV antibodies and the utilization of the Cohn fractionation process and pasteurization procedures, the risk of a recipient receiving HIV infected blood or blood products has diminished significantly, but has not disappeared.[10–12] Screening for antibodies to HTLV-I/II is not routinely conducted. Several IVDUs who donated or sold blood currently test positive for HIV-1 and/or HTLV-I/II. It must be emphasized that there is no way to ascertain the serostatus of these IVDUs at the time of their last donation or sale. Whether any of the blood contributed by these IVDUs became part of the blood supply is unknown, but it is evident that members of this high-risk group continue to donate/sell blood.

The elimination of the sale of blood by IVDUs is a difficult matter. As long as commercial centers exist, IVDUs will attempt to sell their blood. Two characteristics of commercial blood centers facilitate this selling behavior: commercial blood centers which advertise that they pay cash for blood or plasma attract active drug users who do not have stable sources of income; commercial blood centers often are located in inner-city neighborhoods where poverty and drug use are prevalent.

Commercial blood centers must take a more careful approach in the selection of potential sellers. It is imperative that the screening process at commercial blood services be intensified to identify potential sellers who inject drugs or have a history of IV drug use. Commercial blood centers should employ highly qualified individuals, who have had experience with IVDUs, to screen potential sellers for eligibility. Included in the screening process should be a rigorous check for track marks (scarring caused by repeated injections) on arms and other indications of IV drug use.

Drug treatment programs can play an important role in the reduction in the number of IVDUs who donate or sell blood. Educational intervention with past sellers and donors in treatment could have an immediate positive impact.

Blood services, both voluntary and commercial, have an enormous responsibility to exclude IVDUs from their contributor pool. It is incumbent upon these services to staff the blood centers with highly qualified persons who can identify and exclude high-risk persons who continue to donate or sell blood. ☐

Hyperendemic Urban Blastomycosis

A. Cesare Manetti, MD, MPH

ABSTRACT

Within the United States, blastomycosis is primarily endemic in the Mississippi and Ohio River valleys, but reliable figures as to its prevalence and incidence are scarce. A review of pathology department files and medical records from three hospitals in Rockford, Illinois, revealed 32 documented cases of blastomycosis in an eight and one-half year period beginning in March 1981. Twenty-three of these cases were urban since they occurred within the Rockford census tract boundaries—an incidence more than 3.5 times greater than expected in an endemic area. Addresses of patients in 18 of the 23 cases were concentrated at the northeast and southwest ends of the city. Implications are discussed. (*Am J Public Health* 1991;81:633–636)

Introduction

North American Blastomycosis is an elusive, cosmopolitan, systemic infection caused by the dimorphic fungus *Blastomyces dermatitidis.* First described by Gilcrest[1] in 1894, the infection became known as "the Chicago disease" because of the number of cases seen from that area. Later it was referred to as North American blastomycosis as the extent of its wider distribution in the United States and Canada was discovered. Today the disease is correctly and simply referred to as blastomycosis, and its etiologic agent is known to be endemic in Europe, the Middle East, Africa and India. In the Mississippi and Ohio River valleys, where it is primarily endemic, blastomycosis occurs sporadically in humans, dogs and other mammals. Blastomycosis is considered rare, but its true incidence is not known since it is not reportable in most states.

Outbreaks of blastomycosis are seldom observed, and those reported have offered unique opportunities to investigate the source of the infection. The nine outbreaks that have been described to date have mostly been associated with outdoor activities.[2,3] All but one have occurred in non-urban locations, and six were observed in the Great Lakes region. In three of the outbreaks, it was possible to isolate *B. dermatitidis* from rotten wood at exposure sites, mostly in an environment around waterways.[3,4]

One of the most baffling aspects of blastomycosis has been the difficulty encountered in demonstrating where the oganism lives in nature and where humans and animals contract the infection. Any unusual concentration of blastomycosis cases is of interest since it may offer some clues as to the natural habitat of *B. dermatitidis.* This is a report of two hyperendemic foci of blastomycosis in an urban setting.

Methods

Blastomycosis is not a reportable illness in the State of Illinois, nevertheless, a sufficient number of cases came to the attention of the director of the Winnebago County Health Department to suggest the need for an investigation of a possible underlying problem. A search of the files of three Rockford hospital pathology departments and of their respective medical records uncovered 32 cases of blastomycosis. They had all been diagnosed by one or more of three modalities, namely culture, histologic sections and cytologic examina-

TABLE 1—Rockford Hospitals: Blastomycosis Cases [March 1981–August 1989]

Case No.	Specimen (Date/Type)	Census Tract	Age/Race/Sex Occupation	Chief Complaint	Signs, Symptoms and Duration	Initial diagnosis/ Remarks
1	3/81 lung biopsy	2	39, Wh, M factory clerk	Cough	Weight loss, fever	Unresolving pneumonia/ thoracotomy
2	3/81 sputum cytology	28	45, Bl, M factory worker	Cough	Weight loss 5 weeks	Unresolving pneumonia
3	4/81 lung biopsy	13	24, Wh, F secretary	Hemoptysis	Pleural pain	Unresolving pneumonia
4	7/82 skin biopsy	36.01	20, Wh, F	Skin problem		Dermatitis
5	12/82 ear tissue	out of Rockford	25, Wh, M salesman	Ear pain, debility	Weight loss, 3 months	Mastoiditis/ mastoidectomy
6	2/83 bronchial biopsy	out of Rockford	31, Wh, F	Chest pain	Weight loss,	Unresolving pneumonia/ bronchoscopy
7	3/83 bronchial lavage	1.05	31, Wh, M grinder	Cough	Hemoptysis	Unresolving pneumonia
8	3/83 sputum, abscesses	1.05	44, Wh, M teacher	Cough	Weight loss, fever, abscesses lower extremity	Unresolving pneumonia
9	7/83 sputum	out of Rockford	31, Wh*, M factory worker	Cough	Weight loss, fever, chest pain	Unresolving pneumonia
10	12/83 tissue	2	42, Wh, M stock rm clerk	Hemoptysis	Weight loss 4 weeks	Unresolving pneumonia/lobectomy
11	2/85 lung biopsy	out of Rockford	55, Wh, F laborer	Chest pain	7 months	Unresolving pneumonia
12	9/85 lung aspirate	2	33, Wh, M machinist	Cough	Fatigue, chest pain, weight loss	Unresolving pneumonia/suspect blastomycosis
13	4/86 bronchial aspirate	37.03	48, Wh, M mechanic	Cough	Weight loss 2 months	Unresolving pneumonia
14	6/86 lung tissue	1.03	43, Wh, M	Cough	Chills, fever 2 months	Unresolving pneumonia
15	7/86 sputum	out of Rockford	55, Wh, M farmer	Cough	Weight loss, fever	Unresolving pneumonia
16	7/86 lung biopsy	out of Rockford	50, Wh, M factory worker	Cough	Flank pain weeks	Unresolving pneumonia/lung cancer
17	8/86 skin, bone and sputum	out of Rockford	44, Wh, M school coach	Wrist pain	Chest problems months	Synovitis, dermatitis, osteomyelitis, pneumonia
18	8/86 sputum	24	39, Bl, M factory worker	Cough	Chest pain, fever 4 weeks	Unresolving pneumonia/ bronchoscopy
19	4/87 sputum, skin	2	41, Wh, F unemployed	Depression	Chest pain, wt loss, fever 4 months	Psychiatric care, lung infiltrates, skin lesions: dermatitis
20	5/87 sputum	27	47, Bl, M furnace repair	Hemoptysis	Cough, skin lesions	Lung mass, dermatitis
21	10/87 sputum	4.01	89, Wh, M factory worker (retired)	Chest pain		Lung cavity by X-ray
22	11/88 sputum	1.04	38, Wh, F	Hemoptysis	Cough, chills	Unresolving pneumonia
23	12/88 pus, sputum	26	33, Bl, M maintenance worker	Calf abscess	Chills, fever, hemoptysis, weight loss	Abscess pneumonia
24	12/88 sputum	24	26, Bl, M	Cough		Pneumonia
25	1/89 skin biopsy	20	53, Wh, F	Skin lesions	multiple sites	Expired; postmortem miliary blastomycosis
26	2/89 sputum	32	27, Bl, F factory worker	Side pain	Wt loss, fever 5 weeks	Unresolving pneumonia
27	3/89 sputum	out of Rockford	59, Wh, M groundskeeper	Cough	bronchitis, 8 weeks	
28	3/89 sputum	out of Rockford	36, Wh*, F	Cough	Fever, chills	Unresolving pneumonia
29	4/89 joint fluid	34	27, Bl, M construction worker	Elbow pain	Swelling, fever, cough, wt loss 4 months	Osteomyelitis, pneumonia
30	5/89 sputum	32	44, Bl, M unemployed	Cough	Weight loss 6 weeks	Pneumonia
31	7/89 bronchial lavage	5.06	51, Wh, F	Chest pain	Cough, hemoptysis, weight loss	Unresolving pneumonia
32	7/89 trans-bronchial biopsy	22	29, Bl, M	Cough	Chills, fever, weight loss 4 weeks	Unresolving pneumonia

Listing of 32 Rockford blastomycosis cases showing time of diagnosis, census tract and, where applicable, age, race, sex, occupation, chief complaint, signs and symptoms, duration of symptoms at time of initial diagnosis and initial working diagnosis.

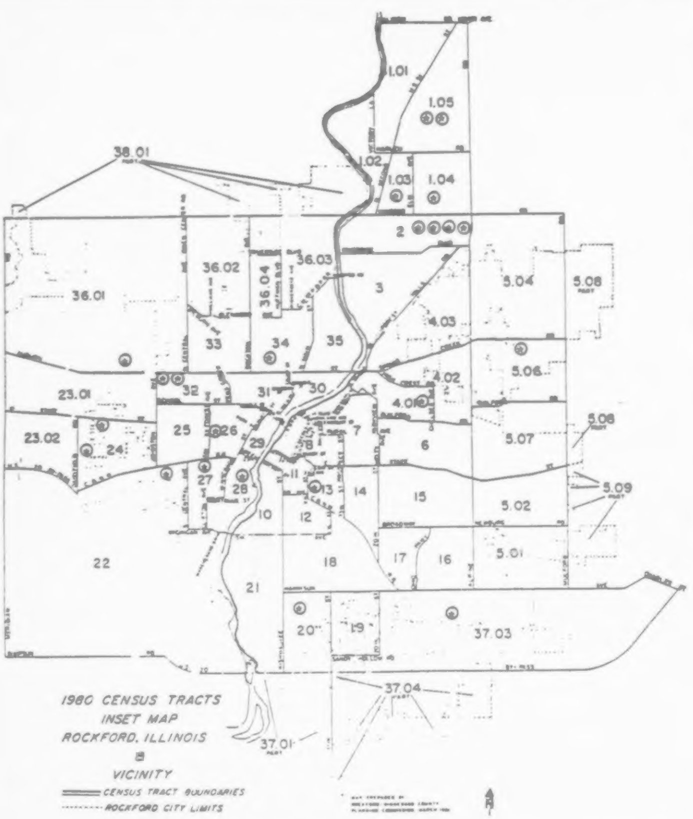

FIGURE 1—1980 Census Tract Inset Map for Rockford and Vicinity in which the Residences of the 23 Urban Rockford Blastomycosis Cases Are Shown Highlighted by a Circled Asterisk.

TABLE 2—Blastomycosis in the City of Rockford (Southwest side) 1980 Population

Census Tract	Total	(Black)	Year	Race	Sex
36.01	2,267	(38)	1982	W	F
34	4,944	(45)	1989	B	M
32	3,965	(1,217)	1989	B	M
			1989	B	F
26	4,452	(2,501)	1988	B	M
24	3,331	(2,402)	1986	B	M
			1988	B	M
22	5,227	(1,960)	1989	B	M
27	3,795	(2,108)	1989	B	M
28	2,153	(1,310)	1981	B	M
Total	30,134	(11,581)		M/F = 8/2	

The 10 cases from one of the two high concentration areas of town are shown according to their specific location, year of occurrence, race and sex. Total and Black population figures per census tract are also given.

tion, during a time span of eight and a half years (from March 1981 to August 1989).

The cases are listed in Table 1 by the month and year when the diagnosis of blastomycosis was first established and by the type of specimen that yielded the diagnosis. The next column gives the census tract in which each Rockford patient lived at the time of initial diagnosis (the patients from other communities are listed as "out-of-Rockford"). Listed in other columns are age, race, sex, occupation, chief complaints, principal signs, symptoms and their duration at the time of initial diagnosis. The initial working diagnosis and other pertinent remarks are given in the last column.

Results

Nine of the 32 patients were referred to Rockford hospitals from outlying areas. Twenty-three patients resided within the census boundaries of Rockford; we will refer to these as the urban areas.

Figure 1 is the 1980 census tract inset map for Rockford and vicinity. In this map, the residences of the 23 urban Rockford cases are highlighted by a circled asterisk.

The distribution of the residences of the 23 Rockford patients was as follows: eight were concentrated in the northeast, 10 were concentrated on the southwest side, and the remaining five were scattered throughout the rest of the city.

The population figures quoted in this study are taken from the 1980 United States Census published in April 1981. According to the Rockford Community Development Department, the population of the city has not appreciably increased or shifted since that time.

Tables 2 and 3 show the 10 cases from the southwest side of town and the eight cases from the northeast side of town according to their census tract, year of occurrence, race and sex, as well as the total population and the black population figures per the 1980 census tract.

Based on the 1980 Rockford census population of 139,712, the annual incidence of blastomycosis in Rockford can be estimated at 1.94/100,000 (23/139,712 × 1/8.5).

Discussion

The following are yearly blastomycosis incidence rates for some states where blastomycosis is endemic[2]:

Arkansas	0.43/100,000
Kentucky	0.44/100,000
Mississippi	0.61/100,000
Wisconsin	0.48/100,000

The estimated incidence rate in Rockford taken as a whole is 3 to 4.5 times the incidence rate for endemic areas, while the estimated incidence in two parts of town is much higher. The annual blastomycosis incidence rates for the south-

TABLE 3—Blastomycosis in the City of Rockford (Northeast side) 1980 Population

Census Tract	Total	(Black)	Year	Race	Sex
1.05	4,242	(81)	1983	W	M
			1983	W	M
1.03	2,654	(5)	1986	W	M
1.04	3,409	(23)	1988	W	F
2	3,807	(8)	1981	W	M
			1983	W	M
			1985	W	M
			1987	W	F
Total	14,112	(117)		M/F = 6/2	

The eight cases from the other high concentration area of town are shown according to their location, year of occurrence, race and sex. Total and Black population figures per census tract are also given.

west side of town is estimated at 3.9/100,000 and that for the northeast area of town is 6.67/100,000—rates which are, respectively, 6 to 9 and 10 to 15 times those reported for endemic blastomycosis.

It should be noted, however, that while the northeast cases all occurred among the predominantly White population, nine out of 10 southwest side cases occurred among the Black minority population, an incidence among Blacks of 9.14/100,000. By contrast, the incidence among Whites inhabiting the same southwest census tract is 0.63/100,000, which is within a reasonable range of the expected endemic incidence.

By the same token, since only five cases of blastomycosis occurred during the same period of time in the population of Rockford living outside of the two high incidence areas, the calculated incidence for these 95,466 individuals is a similar 0.62/100,000.

The present report draws attention to the fact that there can exist foci of a persistent, high concentration of blastomycosis cases in an urban setting. Because of the privileged nature of the hospital records, we were prevented from contacting patients directly to explore further the possible causes of this unusual concentration of cases.

Blastomycosis is a serious, insidious, sometimes indolent disease that frequently goes unrecognized. Eleven of the 50 US states require mandatory reporting of blastomycosis,[5] but many states in a well known endemic area do not, as in the case of Illinois, Indiana, Iowa, Kentucky, Michigan, Missouri, New York and Tennessee.

Given the complexity and serious nature of the condition, we strongly recommend that blastomycosis be included among the reportable infections in Illinois and in neighboring states. ☐

Acknowledgments

This work was prepared in partial requirement for the MPH degree in Community Health Sciences, the University of Illinois, Chicago.

I am indebted to Joseph E. Orthoefer, DVM, for drawing my attention to the problem of Blastomycosis in Rockford. I thank Aquiles Sobrero, MD, Edwin Chen, PhD, and Richard Novak, MD, for their comments on the manuscript. The Winnebago County Health Department and the Medical Record Departments of Rockford Memorial Hospital, Saint Anthony Hospital and Swedish American Hospital were very helpful.

Use of a Medical Center's Computerized Health Care Database for Notifiable Disease Surveillance

Margaret Watkins, BSN, MPH, Sandra Lapham, MD, MPH, and Wendy Hoy, MB, BScMed

ABSTRACT

The sensitivity of a medical center's inpatient and outpatient database to detect notifiable diseases was examined. Only 53 percent of inpatient and 7 percent of outpatient laboratory-confirmed cases of shigellosis, salmonellosis, giardiasis, and hepatitis were identified by an automated search for matching diagnosis codes. Reasons for lack of sensitivity include nonavailability of laboratory results at the time of diagnosis assignment, use of a standardized encounter form with limited preselected diagnosis codes, and pre-empting of the infectious disease diagnosis by other diagnoses. (*Am J Public Health* 1991; 81:637–639)

Introduction

Most communicable disease surveillance systems in the United States are based on passive reporting by health care providers. Because these have major limitations, such as underreporting and reporting bias,[1,2] investigators continue to search for alternative data sources. Promising among these are computerized hospital discharge databases. Although hospital discharge data have been used for disease surveillance,[3,4] questions remain about their validity and sensitivity. This study examines the sensitivity of one medical center's computerized inpatient and outpatient tracking and billing system when used for notifiable disease surveillance. Also assessed was the medical center's completeness of notifiable disease reporting to the health department.

Methods

Lovelace Medical Center in Albuquerque, New Mexico is a 235-bed hospital and multispecialty group practice with eight "satellite" family practice and urgent care centers. During the study period August 1, 1986–July 31, 1987, Lovelace had approximately 10,000 inpatient admissions and 540,000 outpatient visits. A computerized billing system is used to record International Classification of Diseases, 9th Ed, Clinical Modification (ICD-9-CM)[5] diagnosis codes, as well as demographic, diagnostic and billing information. Inpatient codes are assigned shortly after discharge by Medical Records Department staff, based on providers' documentation in discharge summaries and progress notes. Up to 30 diagnosis codes are captured by the system. Outpatient visit codes (both "scheduled" and "urgent care") are assigned at the time of the visit by the medical provider, using a standardized encounter form with pre-selected diagnostic codes. A maximum of three codes is allowed on the outpatient form.

To determine the sensitivity of the ICD-9-CM coding system and to determine the reporting rates to the health department, laboratory-identified cases of five notifiable diseases were used as the "gold standard." These included shigellosis, salmonellosis, giardiasis, and hepatitis A and B. Inpatient and outpatient databases were searched for matching ICD-9-CM codes, and cases of notifiable diseases reported by Lovelace personnel to the New Mexico Health and Environment Department (NMHED) were ascertained. To assess reasons for discrepancies among these data sources, medical record reviews were performed on cases that were laboratory-identified but not reported to the NMHED (n = 44) and cases that were laboratory-identified but not ICD-identified (n = 207). Forty-two of the former (two records not found) were reviewed. Due to resource limitations, a random sample of 60 (29 percent) of the latter cases were reviewed.

Attempts were made to review all non-laboratory-identified cases that were either identified by ICD-9-CM code search (n = 9) or reported to the NMHED (n = 6).

Results

Sensitivity of ICD-9-CM Diagnosis

Each of the three data sources yielded cases that would have otherwise gone undetected (Figure 1). Only about half the inpatient and only 7 percent of the outpatient laboratory-confirmed cases were identified by the matching ICD-9-CM codes (Table 1). However, the ICD-9-CM search identified nine cases—all among outpatients—which were not laboratory-confirmed. None of these were reported to the NMHED. One was a symptomatic contact of a known case, two were

[b] ICD-9-CM—International Classification of Diseases, 9th Ed, Clinical Modification.

chronic or previously diagnosed cases, two were follow-up visits, and one was a case in which the diagnosis—based solely on symptoms—was questionable. (Three records were unattainable.)

Reporting to the Health Department

All inpatient cases and most outpatient laboratory-confirmed cases were reported to the NMHED. Six cases were reported that were not laboratory confirmed; these were symptomatic contacts of known cases or cases in which the diagnosis was based solely on symptoms.

Discussion

Notifiable disease surveillance based solely on ICD-9-CM diagnosis codes was not very sensitive.

In the outpatient setting, miscoding on the initial visit is partly explained by the fact that the laboratory diagnosis has not been established or confirmed. However, medical record review revealed that at the follow-up visit, when positive laboratory results were documented, matching ICD-9-CM codes were still not recorded in approximately half of the cases. Another explanation for the failure to assign appropriate ICD-9-CM codes was the bias introduced by the use of a standardized encounter form with a limited number of preselected diagnosis codes, some of which were nonspecific. The provider seldom uses the option of writing in a diagnosis other than those given on the form. Changes in the encounter form content or usage protocols would be needed before outpatient diagnosis codes would be useful for infectious disease surveillance.

Only half of the inpatient cases were detected by matching ICD-9-CM codes. Review of all the laboratory-identified cases not identified by ICD-9-CM revealed two main reasons for this discrepancy: 1) as with outpatient cases, laboratory results were not always available at the time of discharge, and 2) competing diagnosis; i.e., the infectious disease diagnosis was pre-empted by other diagnoses in complex cases. For example, one patient readmitted with multiple complications after cardiac surgery had 13 discharge diagnoses that did not include his nosocomially-acquired hepatitis B.

Rates of reporting of laboratory-confirmed cases to the NMHED were high. Current policy not only requires that reports of laboratory-confirmed cases are sent to the NMHED, but that salmonella and shigella species isolates are sent to the state scientific laboratory which, in turn, reports to the NMHED. The high rates of reporting of laboratory-confirmed cases documented in this study demonstrate that the system is working efficiently.

Connell, *et al*, have described the opportunities and hazards in the use for research of datasets designed and compiled for other purposes.[6] Our study exemplifies such limitations. Although ICD-9-CM code assignments were not sensitive for detection and surveillance of the notifiable infectious diseases we chose for this study, they were congruent with the clinical picture and may have identified potential cases not detected by laboratory-based surveillance. Conditions whose diagnoses rely predominantly on clinical evidence (e.g., injuries) are likely to be more accurately identified by ICD-9-CM code surveillance. Although further studies on the feasibility of inpatient and outpatient data systems for surveillance are needed, access to a dataset combining laboratory, inpatient, and outpatient information holds potential for disease surveillance. □

Physical Activity on the Job and Cancer in Missouri

Ross C. Brownson, PhD, Jian C. Chang, PhD, James R. Davis, MS, and Carol A. Smith, MSPH

ABSTRACT

We conducted a series of case-control studies to investigate the risks of 16 cancer types in relation to occupational physical activity. These studies were based on Missouri Cancer Registry data for 17,147 White male cancer patients registered between 1984 and 1989. Colon cancer risk was increased for both the moderate (odds ratio (OR) = 1.1; 95% confidence interval (CI) = 1.0, 1.3) and low (OR = 1.2; 95% CI = 1.0, 1.5) activity levels. Similar elevations were observed for prostate cancer at the moderate (OR = 1.1; 95% CI = 1.0, 1.3) and low (OR = 1.5; 95% CI = 1.2, 1.8) levels of activity, and for cancer of the testis at the low activity level (OR = 2.2; 95% CI = 1.3, 3.7). An opposite trend ($p < 0.01$) was noted for lung cancer, which showed decreased risk at the moderate (OR = 0.9; 95% CI = 0.8, 1.0) and low (OR = 0.8; 95% CI = 0.6, 0.9) activity levels. These associations suggest that further study of the relationship between physical activity and site-specific cancer risk is warranted. (*Am J Public Health* 1991;81:639–642)

Introduction

A growing body of evidence suggests an inverse relation between physical activity and risk of colon cancer. Recent studies,[1–11] from diverse populations, have identified an association between occupational or recreational physical activity and colon cancer risk, although one report found no such relation.[12] Elevations in risk of colon cancer in relation to low physical activity have typically ranged from 20-100 percent.[1–11]

Few studies have evaluated the association between physical activity and other types of cancer. Recent findings suggest that physical activity may be associated with several cancer types including cancer of the stomach,[8] prostate,[9] and breast.[10–13]

To investigate the risks of various cancer types in relation to occupational physical activity, we conducted a series of case-control studies based on data from a statewide cancer registry.

Methods

Subjects were identified through the Missouri Cancer Registry for the time period January 1984 through May 1989. The Registry is maintained by the Missouri Department of Health and has been collecting data on incident cancer cases from public and private hospitals since 1972. Hospital reporting has been mandated by law since 1984. Reporting procedures and validity issues have been discussed in more detail elsewhere.[14]

The current study involved a series of case-control studies that included White male cancer patients who were 20 years of age or older at the time of diagnosis. Men with cancer of ill-defined and unknown primary sites (*International Classification of Diseases for Oncology*[15] (ICD-O) codes 195 and 199) were excluded. Selection was limited to White males due to the small

number of other races and the lack of occupational diversity among females.

Data on occupation and tobacco use are routinely abstracted from the hospital medical record at the time of diagnosis for the Missouri Cancer Registry. Hospital registrars record employment information for cancer patients using a standardized protocol. These data are subsequently coded by trained cancer data specialists on the Registry staff using the three-digit 1980 US Census codes.[16] The smoking history of each patient is characterized according to status (i.e., never, former, or current use) and, among current smokers, according to the number of packs smoked per day.

Analysis was limited to 17,147 subjects from the Registry who had codable occupational information. The remaining subjects had no occupational information or noninformative job titles such as "retired."

The classification scheme of Garabrant *et al.*[1] with modifications for Missouri work requirements,[11] was used to categorize occupations according to the level of physical activity. Individual occupations were classified according to whether physical activity is required more than 80 percent of the time (high activity), 20–80 percent of the time (moderate activity), or less than 20 percent of the time (low activity). Subjects were then assigned to one of the three activity levels.

In the analysis for each cancer site, all other cancer registrations formed the control group. For example, in the analysis of the buccal cavity (ICD-O codes 140-149), the case group consisted of 585 patients with this cancer type and the control group consisted of 16,562 "other" cancer patients. The distribution of study subjects by cancer type is shown in Table 1.

Maximum likelihood estimates of the odds ratio (OR)[18] were adjusted for age and smoking, and trend tests were conducted.[19] The highest level of activity was used as the reference category.

In calculating site-specific ORs, colon cancer was excluded from the control group since physical activity has been consistently shown to be a risk factor for colon cancer.[1–11] In addition, because some nonsedentary jobs may be at increased risk of lung cancer due to carcinogenic exposures, ORs for physical activity and lung cancer were adjusted according to *a-priori* job assignments. Occupations were assigned to a high-risk or low-risk category based on a previous study of occupation and lung cancer in Missouri.[20]

Results

Table 2 presents the risks of various cancer types according to the level of occupational physical activity. Elevated colon cancer risk was observed for both the moderate (OR = 1.1; 95% confidence interval (CI) = 1.0, 1.3) and low (OR = 1.2; 95% CI = 1.0, 1.5) levels of activity, with an inverse trend ($p = 0.05$) in risk. Among anatomic subsites of colon cancer, risk was highest for cancer of the cecum, with an OR of 1.3 (95% CI = 0.9, 1.9) at the moderate activity level and an OR of 1.8 (95% CI = 1.0, 3.0) at the low activity level.

Similarly, prostate cancer showed increased risk for moderate (OR = 1.1; 95% CI = 1.0, 1.3) and low (OR = 1.5; 95% = 1.2, 1.8) activity levels. Elevated risk of cancer of the testis was noted for the low activity level (OR = 2.2; 95% CI = 1.3, 3.7). Inverse linear trends were observed for cancers of the prostate ($p < 0.01$) and testis ($p < 0.01$).

An opposite trend ($p < 0.01$) was seen for lung cancer. Decreased risk was shown for moderate (OR = 0.9; 95% CI = 0.8, 1.0) and low (OR = 0.8; 95% CI = 0.6, 0.9) activity levels. Of the major histologic types of lung cancer, the strongest gradient in risk was shown for squamous cell carcinoma. For this cell type, the OR for moderate activity was 1.0 (95% CI = 0.8, 1.1) and the OR for low activity was 0.6 (95% CI = 0.4, 0.8), with a significant gradient in risk ($p < 0.01$).

Discussion

This study corroborates recent studies[1–11] that suggest a relation between low physical activity and colon cancer risk although risk estimates were lower than those reported in some previous studies. Other possible associations were identified between physical activity and cancers of the prostate, testis, and lung.

The physiologic mechanism by which physical activity decreases colon cancer risk is not yet clearly defined but it may relate to increased colon peristalsis[21] and a subsequent decrease in the transit time of the stool and the accompanying exposure of the colon to fecal carcinogens.[4] In addition, experimental animal studies suggest a decreased incidence and growth of induced and transplanted tumors associated with higher levels of physical activity.[22,23]

We found inverse associations between occupational physical activity and cancers of the prostate and testis. Albanes *et al.*[9] recently reported a significant inverse relation between recreational exercise and prostate cancer risk. Previous studies of occupational mortality from Washington State[10] and among San Francisco longshoremen[12] have shown some evidence of a relation between prostate cancer and low job activity. However, other studies[8–12] have shown little evidence of a physical activity-prostate cancer association. The only previous study that investigated physical activity and can-

*Adjusted for age, smoking, and carcinogenic job assignment (lung cancer only); the high activity level was the reference category.

cer of the testis was the study of Harvard and University of Pennsylvania alumni[12] in which no association was observed.

We found a positive association between occupational physical activity and lung cancer risk, although uncontrolled confounding for smoking habits may be partially responsible for this relationship. Earlier studies[8,9,12] have shown a general tendency toward decreased lung cancer risks associated with various measures of higher physical activity levels, although findings have not been entirely consistent.

Severson *et al.*[8] recently reported an increased risk of stomach cancer in relation to several measures of physical activity. These Missouri data showed no evidence of a physical activity-stomach cancer association. We found a slight association between low physical activity and rectal cancer risk, which has been reported inconsistently in previous reports.[1,2,8–10,12]

Our study has several limitations. We used occupational information collected in conjunction with cancer incidence reporting to produce a surrogate measure of physical activity. However, a recent study[14] that compared risk factor information contained in the Registry record with that obtained by interview found reasonable agreement for occupational data. We were also unable to adjust for some potential confounders such as socioeconomic status and dietary history. Although we lacked information on avocational physical activity, it has been reported that the majority of total physical activity in American workers occurs on the job.[24]

Major strengths of our study are the greater accuracy in hospital-reported tumor diagnosis, compared with death certificates,[25] and the ability to analyze data by histologic type or by anatomic subsite.

Our findings for cancers of the prostate, testis, and lung should be considered preliminary and require confirmation in other studies with more detailed measurements of physical activity and potential confounders. ☐

Acknowledgments

The authors are grateful to the staff of the Missouri Cancer Registry for assistance with data review, coding, and entry. They also thank Dr. David H. Garabrant of the University of Southern California School of Medicine for providing the occupational physical activity classification scheme.

Health Care Received by American Children: NCHS Report

The vast majority (83 percent) of American children are covered by health insurance, have a regular source of health care (88 percent, and visited a doctor in the past year for routine health care (64 percent) according to a recent report issued by the National Center for Health Statistics. The report cites new evidence, however, that America's minority and poor children receive less care, including preventive services.

The report—*Health Insurance and Medical Care: Health of Our Nation's Children, United States 1988*—is derived from data from the 1988 National Health Interview Survey on Child Health, conducted by NCHS. Questions on health insurance and sources of medical care were requested for all 17,110 children in a nationally representative sample of children 17 years of age and under.

The survey shows that Black newborns and infants were two to three times more likely to have lacked a routine visit for a check-up or any immunization during the first year of life than were White newborns and infants. Hispanic children were twice as likely to have no health insurance coverage, either public or private, as non-Hispanics.

Most children with a regular source of health care had private care; however, 16 percent of those children (8.7 million) received health care from hospital clinics, emergency rooms, walk-in or emergency centers or other clinics. Clinics were the source of care for 47 percent of Black infants, compared to 16 percent of White infants. For Hispanic infants, almost half received health care in clinics.

The report, *Health Insurance and Medical Care: Health of Our Nation's Children, United States, 1988*—is available from the National Center for Health Statistics, Centers for Disease Control, US Public Health Service, 6525 Belcrest Road, Hyattsville, MD 20782; (301) 436-8500.

Vietnam Era and Vietnam Combat Veterans among the Homeless

Robert Rosenheck, MD, Peggy Gallup, PhD, and Catherine A. Leda, MPH, MSN

ABSTRACT

Of 10,524 homeless veterans assessed in a 43-site VA program, 50 percent served during the Vietnam War era, compared to only 29 percent of all veterans in the general population. This reflects the greater risk of homelessness among men aged 30-44 rather than the impact of Vietnam Era service. The proportion of homeless veterans who served in the Vietnam Theater (44.9 percent), and the proportion exposed to combat fire (40.5 percent) were similar to those of nonhomeless veterans. Homeless combat veterans who are not White were more likely to have psychiatric, alcohol, and medical problems than homeless noncombat Vietnam veterans who are not White. (*Am J Public Health* 1991;81:643–646)

Introduction

Surveys of the homeless have indicated that 43 percent to 50 percent of homeless male veterans served in the military during the Vietnam Era (August, 5, 1964-May 7, 1975),[1-3] compared to only 29 percent of veterans in the general population.[4] During the 1980s, reports of high percentages of Vietnam Era veterans among the homeless appeared virtually simultaneously with a growing body of literature reporting significant post-war readjustment problems among Vietnam combat veterans[5,6] and suggested that veterans who served in Vietnam may be at particularly high risk for homelessness.

Three important shortcomings of these initial studies were: 1) the numbers of Vietnam Era veterans studied were small (53-88 per study); 2) the potentially confounding influence of age was not addressed (Vietnam Era veterans fall into the age cohort that is most at risk for homelessness)[7] and 3) data were not presented on exposure to the presumed combat stressors, whether service in the Vietnam theater of war or exposure to life-threatening combat fire.

In 1987-88, the Department of Veterans Affairs (VA) Homeless Chronically Mentally Ill Veterans Program conducted intake assessments on 10,524 homeless veterans, of whom 5,287 (50 percent) reported service during the Vietnam Era. In this paper, demographic, military service and clinical assessment data on these veterans, and published data on Vietnam Era veterans in the general population, are used to examine: 1) whether Vietnam Era veterans are disproportionately represented among homeless veterans, when age is taken into consideration; 2) whether homeless Vietnam Era veterans are more likely to have served in Vietnam or to have been exposed to combat fire in Vietnam than Vietnam Era veterans in the general population; and 3) whether homeless veterans who served in Vietnam or who were exposed to combat fire there have more frequent medical, psychiatric or substance abuse problems as compared to a reference group of homeless veterans who did not serve in Vietnam.

Methods

Subjects

The Homeless Chronically Mentally Ill (HCMI) Veterans Program was implemented in May 1987, at 43 VA Medical Centers across the country. Sites were selected on the basis of the estimated number of homeless persons in their service area, their capacity to conduct outreach to the homeless and the presence of a coalition of agencies assisting the homeless in their area.

Homeless veterans were contacted through several routes: 52.7 percent were contacted through community outreach efforts in which social workers and nurses visited shelters, soup kitchens and other places frequented by the homeless, seeking out veterans in need of assistance; 26.1 percent came to VA facilities on their own; 13.3 percent were referred by non-VA programs for the homeless; and 7.9 percent came through unspecified routes. Veterans were offered intake assessments if they were judged to be eligible for VA benefits, lacked a conventional place to sleep, and expressed interest in VA health care services or other benefits.

Procedures

A standardized intake form recording data gathered through a structured interview, and clinicians' observations of major psychiatric symptoms, was completed on veterans assessed during the first 10.5 months of program operation (May 15, 1987-March 30, 1988). The interview addressed self-reported age, gender, ethnicity, duration of the current episode of homelessness, dates of admission and discharge from military service, receipt of combat pay, exposure to fire during com-

*VA Annual Report, 1989.
+data missing on 331 veterans.

bat service, and past history of psychiatric and substance abuse hospitalization. Alcohol and drug abuse problems were identified through a combination of patient self-reports (e.g., "Do you have a problem with alcohol dependency now?") and clinician observations. Major psychiatric problems were assessed with a 10-item summed Psychiatric Problem Index (PPI), consisting of three self-report items and seven clinical observations, (Cronbach's alpha = 0.71). On a sub-sample of 1,318 veterans asssessed in this Program, a PPI of two or more was associated with a major DSM-III psychiatric disorder (schizophrenia or other psychosis, bipolar disorder or depressive disorder), as determined by a psychiatrist's examination, with a sensitivity of 80.1 percent and a specificity of 58.0 percent. A score of two or more on the PPI was thus considered evidence of significant psychiatric disorder.

Military service during the Vietnam Era was categorized as follows. All veterans who served between August 7, 1964 and May 5, 1975 are officially classified by VA as *Vietnam Era* veterans. Within this group, *Vietnam Era Only* veterans (those who did not serve in Vietnam, and who were not exposed to warzone stress) were distinguished from *Vietnam Theater* veterans. Within the group of Vietnam Theater veterans, *noncombat exposed* veterans (those who served in Vietnam but were not under fire) were distinguished from *combat exposed* veterans.

Published data on veterans in the general population were used for comparison purposes and included the Census Bureau's 1987 civilian population estimates[4] and the Third Survey of Veterans,[8] a 1987 survey of a national sample of 9,442 veterans.

Comparisons were made between the proportions of homeless veterans in various age and military service categories and estimated proportions of veterans in the general population in those categories. In addition, health status indicators for noncombat-exposed and combat-exposed Vietnam Theater veterans were compared with health status indicators for veterans who did not serve in Vietnam. Measurement precision was expressed as the 95 percent confidence interval of differences in percentages.

Results

Veteran Characteristics

Age Distribution: All Service Eras: The median age among *all* veterans in the HCMI Program was 40.1 years; 54.3 percent were 30-44 years old (Table 1). Homeless veterans in this program were thus similar in age to other homeless Americans who have a median age of 36.1 years.[7] In contrast, the median age among veterans in the general veteran population in 1987 was 54.4 years; only 26 percent were 30-44 years old. Among veterans, as in the general population,[7] the largest percentages of the homeless are in their 30s and early 40s.

Vietnam Era Service: Over half of all veterans in the HCMI Veterans Program served during the Vietnam Era, compared to only 29 percent in the general veteran population. However, within matched five-year age cohorts, the percentages of Vietnam Era veterans in the HCMI Veterans Program were generally similar to those in the general veteran population, although among the homeless, greater percentages of Vietnam Era veterans were found within younger age cohorts (Table 2). Among both homeless veterans and veterans in the general population, over 80 percent of 30-44 year-olds were Vietnam Era veterans (87 percent in the HCMI Veterans Program; 81 percent in the general veteran population).

Characteristics of Vietnam Era Veterans: Vietnam Era veterans were 99 percent male; 54.6 percent White; 36.8 percent Black; 6.9 percent Hispanic; and 1.7 percent other. The racial distribution was similar to that reported in other studies of the homeless.[7] The duration of the current episode of homelessness was less than one month for 25.8 percent, from one month to one year for 43.9 percent and more than one year for 30.3 percent.

Vietnam Theater Service: Among Vietnam Era veterans assessed by the HCMI Veterans Program 44.9 percent reported service in the Vietnam Theater; 40.5 percent reported exposure to combat and 4.4 percent reported no combat exposure. These proportions are quite similar to those of Vietnam Era veterans in the general population, among whom 48.7 percent report service in the Vietnam Theater; 38.4 percent report exposure to combat and 10.3 percent report war zone service but no combat exposure.[8]

The percentage of White homeless Vietnam Era veterans who reported service in the Vietnam Theater was somewhat greater than that of other racial-ethnic groups (46.2 percent vs 42.4 percent). In contrast, in the general population of veterans 48.0 percent of Whites report service in the Vietnam Theater compared to 52.1 percent of other racial-ethnic groups.

Clinical Assessment of Homeless Vietnam Era Veterans: Among homeless Vietnam Theater combat veterans who were not white, current medical, psychiatric and alcohol problems, as well as past histories of psychiatric hospitalization, were more common than among noncombat homeless veterans of similar race-ethnicity (Table 3). While the same trends were apparent among Whites, they were of lesser magnitude.

TABLE 2—Proportion of Veterans Who Served During the Vietnam Era by Five-year Age Cohorts: HCMI Veterans Program (May 15, 1987–March 31, 1988) and All US Veterans, 1987

Age Cohort (Years)	HCMI Veterans Program N = 10,193	All US Veterans N = 28,688,000*
	%	%

Past Alcohol Hospital	38.6	42.4	3.7 (−0.4,7.8)
Past Drug Hospital	26.0	26.3	0.3 (−3.4,4.0)

Discussion

Several methodological limitations of this study require comment. Although the data were collected in a national program, they were not gathered through a systemic sampling procedure and findings cannot be confidently generalized to the national population of homeless Vietnam Era veterans. Both sampling and reporting biases may influence our findings. First, data were collected through a VA clinical program, in which an over-representation of combat-stressed veterans might be expected. Second, because the data were gathered in a VA program, veterans may have tended to overreport their combat experiences, assuming that such reports would improve their access to VA health care services and financial benefits. On the other hand, many Vietnam veterans have been critical of VA services,[9] and some have been reluctant to use them,[10] possibly biasing the representation of Vietnam Theater veterans downward. In our view, Vietnam service is more likely to have been overcounted in this study than undercounted.

The data presented suggest that the large percentage of Vietnam Era veterans among homeless veterans is best explained by the specific vulnerability of men in their 30s and early 40s to homelessness.[7] Neither Vietnam Era service, Vietnam Theater service, nor exposure to combat fire appear to be unexpectedly common among homeless veterans studied.

This conclusion is consistent with findings from the National Vietnam Veterans Readjustment Study (NVVRS),[6] conducted in 1987. The NVVRS did note, however, that veterans who met diagnostic criteria for Posttraumatic Stress Disorder (15.2 percent of all Vietnam Theater veterans) were far more likely to have been homeless than those who did not. While Vietnam service, by itself, does not appear to be a major risk factor for homelessness, those veterans who were most affected by combat may be at greater risk for homelessness than others.

Vietnam veterans in the HCMI Veterans Program who were not White and who were exposed to combat have more frequent psychiatric, medical and alcohol problems than those veterans who are not White who did not serve in Vietnam. These findings are consistent with those of the NVVRS which found substantial differences in health status measures between veterans who were exposed to high levels of combat and those not exposed, and a considerably higher prevalence of Posttraumatic Stress Disorder among those who are not White than among Whites.[6] The absence of significant differences in health status measures among Whites may reflect the limited specificity of our screening instruments, although further research is needed to clarify the meaning of these findings. While not overrepresented among homeless veterans, homeless Vietnam combat veterans, like Vietnam combat veterans examined in other studies, appear to face more frequent medical and psychiatric problems and may require special services. ☐

Determinants of Late Stage Diagnosis of Breast and Cervical Cancer: The Impact of Age, Race, Social Class, and Hospital Type

Jeanne Mandelblatt, MD, Howard Andrews, PhD, Jon Kerner, PhD, Ann Zauber, PhD, and William Burnett, MD

ABSTRACT

Previous studies of the relationship between cancer stage, age, and race have not controlled for social class and health care setting. Logistic regression analyses, using information from the New York State Tumor Registry and area-level social class indicators, demonstrated that, in New York City, older Black, lower class women in public hospitals were 3.75 and 2.54 times more likely to have late stage breast or cervical cancer, respectively, than were younger White, high social class women in non-public hospitals. (*Am J Public Health* 1991;81:646–649)

Introduction

Age and race have each individually been associated with cancer stage.[1–5] However, previous studies have not controlled for the effects of social class and health care setting. This paper presents findings from logistic regression analyses to quantify the individual and combined effects of age, race, socioeconomic class, and type of health care setting on breast and cervical cancer stage.

Methods

Cancer Data-Tumor Registry

The study sample consisted of all cases of breast and cervical cancer among New York City (NYC) residents that were reported to the New York State Department of Health Tumor Registry between 1980 and 1985. More than 90 percent of incident cases are reported to the registry from NYC.[6] In the study period, there were 22,111 breast cancer, 2,930 invasive cervical cancer, and 6,408 cervical carcinoma in-situ cases with known stages reported. Stage was unknown for 7.5 percent and 2.6 percent of the breast and cervical cases, respectively. Missing stage was associated with age ($p < .0001$) and missing marital status ($p < .01$) for both cancers. Age was classified into five-year categories. Race was reported as either Black or White. There were insufficient data to include Hispanic origin in the analysis. Marital status was dichotomized as "ever" versus "never" married. Hospital type was classed as "public" for the 11 NYC municipal hospitals and "non-public" for the remaining facilities.

Demographic Variables—Census Data

Because individual information on socioeconomic class is not available in registry data, 1980 United States census

TABLE 1—Sample Characteristics for Cases Used in Each Model

Characteristics	Model 1 Breast Late vs Early	Model 2 Breast Distant vs Regional	Model 3 Cervical Late vs Early	Model 4 Cervical Invasive vs In-Situ
Number of Cases[a]	19,132	9,991	2,343	7,182
State (% Late)	52.2	NA	45.1	32.6
Age in years, mean (S.D.)	79.5	60.6 (13.92)	52.4 (15.40)	41.7 (15.8)
Race (% Black)	17.6	20.0	41.0	36.8
Hospital (% Public)	6.1	7.7	16.1	14.0
% Ever Married	84.5	84.3	80.4	70.5
% High School[c], mean (S.D.)	62.3 (16.4)	61.0 (16.2)	54.8 (16.2)	57.3 (17.2)
Median Family Income[c], mean (S.D.)	$16,139 (6,427)	$15,756 (6,333)	$12,966 (5,746)	$13,796 (6,190)

a) The number of cases having complete data for all variables.
b) Percent post-menopausal.
c) These variables were added to the NYS Tumor Registry data set using values for the census tract in which the case lived.

TABLE 2—Summary of Logistic Regression Analysis: Prediction of Late Stage Breast Cancer

	Late vs Early		Distant vs Regional	
Variables	Regression Coefficient	Odds Ratio (95% Confidence Interval) (p-value)	Regression Coefficient	Odds Ratio (95% Confidence Interval) (p-value)
Age[a]	.086	1.09 (1.02, 1.17) (p < .015)	.086	1.09 (1.08, 1.11) (p < .001)
Race (1 = White, 2 = Black)	.215	1.24 (1.14, 1.35) (p < .001)	−.083	.92 —[c] (p < .15)
Hospital Setting (0 = non-public, 1 = public)	.412	1.51 (1.32, 1.71) (p < .001)	.322	1.38 (1.18, 1.62) (p < .001)
Marital Status (0 = never, 1 = ever)	−.041	.96 —[c] (p < .369)	−.357	.70 (.63, .79) (p < .001)
Income[b] ($5,000 increments)	.029	1.03 —[c] (p < .055)	−.020	.98 —[c] (p < .482)
Education[b] (% high school, 5% increments)	−.051	.95 (.94, .96) (p < .001)	−.030	.97 (.95, .99) (p < .002)
Intercept	.29		−.96	

a) All age in 5-year intervals, except late vs early breast, which is post vs pre-menopausal.
b) Note: These are continuous variables and the odds ratios represent the increased risk for each incremental increase in the variable, compared to the next lowest level of the variable.
c) Confidence interval includes one.

data on the median family income and the percent of adults with a high school education in the census tract of residence of the case were used as social class measures.

Logistic Regression Models

Two models were developed for each cancer based on groupings with similar treatment patterns. For breast cancer, the first model predicted the outcome of late stage (regional and distant) compared to early stage (localized and in-situ). As a result of recent advances in the treatment of regional disease, a second model was developed comparing distant to regional disease. For cervical cancer, the outcome of the first model was late stage (regional and distant) versus early stage (localized) invasive cancer. In addition, invasive and in-situ disease were compared in a second model as a measure of the success of Pap screening. For all models the independent variables were age, race, marital status, hospital type, income, and education. Logistic regression models were developed using SAS programs. Table 1 presents summary statistics for the cases included in the models.

Results

The logistic regression analysis indicated that, controlling for the other variables, the following factors were associated with late stage breast cancer: postmenopausal age, Black race, low education, and public hospital use (Table 2). Lower income was also weakly associated with late stage ($p < .055$). In the second model, age, public hospital use, marital status, and low education were each associated with an increased risk of distant disease.

Regression coefficients and intercepts from each model were used to calculate the odds of late stage disease for combinations of variables (Table 3). For example, the odds of having distant, compared to regional, breast cancer were 4.77 times higher for a Black woman who was age 70 to 74, unmarried, in the lowest income and education groups, and who used the public hospital system, compared to a White married woman age 40 to 44, in the highest income and education groups, using a non-public hospital.

For invasive cervical cancer, age and public hospital setting were each associated with an increased risk of late stage disease (Table 4). In the second model, age, race, hospital setting, income, and education were each associated with invasive disease.

The composite odds of a 70 to 74 year old, unmarried Black woman in the lowest income and educational group who used the public hospital system having late stage invasive cervical cancer were 2.54 times greater than for a White, married, 40 to 44 year old woman in the highest income and educational levels and using a non-public hospital (Table 5). The odds for

TABLE 3—Risk of Late Stage Breast Cancer for Women of Differing Demographic Profiles

	Late vs Early[a]	Distant vs Regional[b]
	Odds Ratio[c]	Odds Ratio[c]
Profile 1: Base Case[d]		
70–74 years, Black, poor, low education, public hospital, unmarried	3.75	4.77
Profile 2: Young		
40–44 years, Black, poor, low education, public hospital, unmarried	3.43	2.82
Profile 3: White		
70–74 years, White, poor, low education, public hospital, unmarried	3.02	not significant[e]
Profile 4: Non-public hospital		
70–74 years, Black, poor, low education, non-public hospital, unmarried	2.49	3.46
Profile 5: 90% High School		
70–74 years, Black, poor, high education, non-public hospital, unmarried	2.04	3.33

a) The minimum odds for the lowest risk case (a pre-menopausal, White, married woman using a non-public hospital and living in a community where 90% of the adult population completed high school and the median income is $40,000 per year) is .67.

b) The minimum odds for the lowest risk woman (a 40–44 year old, White, married woman using a non-public hospital and living in a community where 90% of the adult population completed high school and the median income is $40,000 per year) is .35.

c) Odds ratios are computed from the division of the maximum odds by the minimum odds. Minimum and maximum odds are calculated using regression coefficients from the logistic models.

d) Low education and education represent living in a community where 30% of adults completed high school and the median income is $10,000 per year.

e) The variable of interest was not significant in the original regression model.

a woman of the same profile having invasive compared to in-situ disease were 39.75 times higher than for her younger, White, non-disadvantaged counterpart.

Discussion

This study demonstrates that elderly, Black, lower socioeconomic status (SES) women who use public hospitals are at extremely high risk of having their breast and cervical cancers diagnosed at late stages. While our findings are consistent with and extend the findings of prior researchers,[1-5] there are two caveats that should be considered in evaluating our conclusions.

First, in our analysis missing stage was associated with age. However, since older women with advanced disease are less likely to be staged than younger women,[7,8] the missing stage information is likely to underestimate the observed effect of age on stage.

Second, since the NY State Tumor Registry does not contain social class indicators, we assigned to each woman the median income and educational level of her community of residence. While we have no way to determine the relationship of the individual and community SES indicators, several studies of cancer incidence and/or mortality have used group-level data to define socioeconomic status[9-15] and have drawn similar conclusions to studies that use individual information.[16-19] Group data can also capture characteristics of the individual's social "context" which may provide information about class gradients that may not be reflected by individual characteristics.[20,21] It is possible that hospital type is serving as such a "contextual" measure in our analysis.

Our findings suggest that cancer control interventions targeted to elderly disadvantaged women, particularly those of color and those who use public hospitals, have the potential to decrease avoidable cancer morbidity and mortality. ☐

Public Health and the Law

The Effect of Mandatory Premarital HIV Testing on Marriage: The Case of Illinois

Background

In the past 10 years, AIDS (acquired immunodeficiency syndrome) has become a dominant public health concern. During the late 1980s, state governments took steps to counter the health threat of AIDS. One of the most controversial was the requirement of the State of Illinois that applicants for marriage licenses be tested for human immunodeficiency virus (HIV) antibodies. Among the states, Illinois and Louisiana adopted mandatory premarital testing; only in Illinois was a law implemented for a significant length of time.[1]

Effective January 1, 1988, the Illinois marriage law was amended to require a physician's statement on HIV testing be submitted to the county clerk before a marriage license could be issued. The statement affirmed that both parties to the marriage were tested for HIV antibodies and advised of the test results. The HIV testing requirement was one of a number of AIDS-related measures adopted by the state legislature. In this case, the feeling that people getting married ought to know about HIV infection and the absence of a direct cost to the state was persuasive to lawmakers.[2] The HIV testing requirement was repealed in September 1989.

At the time it was introduced, premarital testing was controversial. Mandatory testing was opposed by the Centers for Disease Control (CDC) and various medical groups.[3,4] Simulation indicated that mandatory premarital testing would be very expensive[5] and probably no more cost-effective for case identification than testing for syphilis.[6]

Upon implementation, the HIV testing requirement was said to depress the frequency of marriages in Illinois. Media reports indicated that couples were crossing state lines to avoid the test,[7] although some observers thought the drop in marriages might be permanent:

> It is ironic that the Illinois screening program has discouraged many people from entering into a legal commitment that fosters a mutual monogamous relationship.[8,9]

This report investigates the hypotheses: (a) that mandatory premarital HIV testing decreased marriages in Illinois; and (b) that the requirement increased crossover marriages in states bordering Illinois. Additional analyses investigated the claim that the frequency of marriages in Illinois has rebounded now that premarital testing is no longer mandatory.[10]

Methods

Illinois Premarital Testing Law

For roughly 20 months, from January 1, 1988 through September 10, 1989, Illinois marriage law required a physician's statement that both parties to the proposed marriage were tested for HIV antibodies and advised of the test results be submitted to the county clerk before a marriage license could be issued.[11] The tests must have been administered within 30 days of the license application. The license was good for 60 days. Positive results on the initial enzyme-linked immunosorbent assay (ELISA) test were to be followed by the Western Blot Assay. A person was considered seropositive for HIV virus if he or she was positive on both tests. Seropositive results were to be reported to the Illinois Department of Public Health.[12]

Table 1 presents marriage license requirements for the seven states included in this study at the time the Illinois premarital testing law became effective.[13] Illinois, like two of the bordering and two of the comparison states, required a blood test for syphilis. In Illinois the marriage license became effective the next day; all the other states had longer waiting periods, although in two bordering and two comparison states, these periods could be waived.

TABLE 1—Marriage License Requirements in Seven States, 1987

State	Blood Test	Waiting Period
Illinois	Yes	Marry next day
Indiana	Yes	72 hours
Wisconsin	Yes	5 days, waivable
Missouri	No	3 days, waivable
Ohio	Yes	5 days
Minnesota	No	5 days, waivable
Kansas	Yes	3 days, waivable

Marriage Time Series

Monthly marriage times series were investigated for seven states for the period from January 1980 through August 1989[14]: (a) Illinois; (b) Indiana, Wisconsin, and Missouri, the three states bordering Illinois largest MSAs (metropolitan statistical areas) that would be expected to show crossover increases; and (c) Ohio, Minnesota, and Kansas, three comparison states

This paper was accepted for publication on August 30, 1990 by George J. Annas, JD, MPH, editor of the Public Health & the Law column, and Professor of Health Law, Boston University, School of Public Health, 80 East Concord Street, Boston, MA 02118.

that do not border Illinois and were not expected to show crossover effects. The beginning of the study period was chosen to allow a long enough pre-HIV-testing series to estimate cyclical trends. August 1989 was selected as the final observation because the law was repealed in mid-September 1989.

Monthly marriage frequencies are collected by state health officials and reported to the National Center for Health Statistics (NCHS) which publishes them on a monthly, "provisional" basis. These time series are labeled "provisional" because non-regular reporting schedules across the states require occasional adjustments to published data. During the first half of the study period, these adjustments were noted in the reports. This practice has not been maintained. Marriages are reported by state of occurrence, not by the state in which couples reside.

Primary NCHS interest is in aggregate data, not in maintaining monthly series on a state-by-state basis. Experience indicates that adjustments more likely reflect a random pattern than consistent practice in any of the states.[15] This type of variation in the time series represents a threat of Type II (unreliability) rather than Type I error (history or instrumentation) for the present study. Because of the statistical analysis procedures, monthly time series were used rather than the more stable but less diagnostic yearly time series.

Statistical Analyses

Box-Jenkins ARIMA interrupted times-series analysis[16] was used because of its ability to estimate cyclical trends and to provide unbiased statistical tests of the impact of the premarital testing law. Using this technique, trend and serial dependency parameters first were estimated for the 96 pre-HIV-testing months, January 1980 to December 1987, for each of the seven states. Next an interruption model is tested for the full time series (including the 20 months from January 1988 to August 1989 when HIV testing was required in Illinois). In addition to trend and serial dependency components, the interruption model includes a binary time series (e.g., 000011111) with 0 values for months during the pre-HIV-testing period and with 1 values for testing months. This Testing Law parameter estimates the size and form (if any) of change in the marriage time series at the point when mandatory premarital HIV testing was introduced in Illinois.

Both permanent/temporary, and abrupt/gradual interruption models were tested for all seven states. Only the permanent, abrupt model results are reported (where appropriate) because only this model yielded statistically significant and appropriate testing law parameters. A permanent, abrupt interruption model shifts the level of the time series only at the point of intervention. This shift is maintained for the duration of the intervention.

Three measures of goodness of fit are available for testing models in Box-Jenkins ARIMA times-series analysis,[16] two of which have counterparts in normal multiple regression analysis. Individual parameters are tested for statistical significance by t-tests and overall R^2 is computed for the full models. This R^2 value is generally much larger for times series analysis than is typical for normal multiple regression analysis. A chi-square test is also made of the residual autocorrelation function. This test estimates whether reliable variation remains among the time series observations. Statistical analyses used the 1984 version of the BMDP 2T Box-Jenkins Times Series program.[17]

Results

Decrease of Marriages in Illinois

Figure 1 presents the raw marriage time series for Illinois. Note the recurrent seasonal cycle, marriages up in Summer and down in Winter. The first hypothesis asked whether the time series moved down as a result of premarital HIV testing. Inspecting Figure 1, this hypothesis expects that marriage frequency is lower starting January 1988 than before this date.

The top row of Table 2 presents the results of statistical analyses relevant to the hypothesized drop in marriages in Illinois. The statistically significant seasonal trend component indicates that, over the 10 years studied, marriages in Illinois decreased by 241 a month on a yearly basis (e.g., January 1980 to January 1981). The model also has statistically significant moving average and autoregressive components that are not presented. The statistically significant testing law parameter reveals an abrupt decrease of 1,043 marriages in Illinois in January 1988 when premarital HIV testing became mandatory.

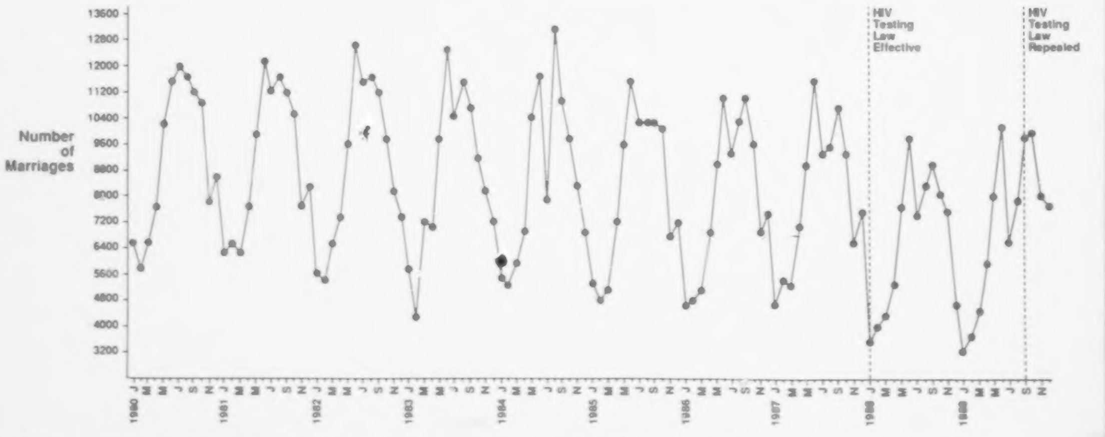

FIGURE 1—Monthly Marriage Time Series for Illinois from January 1980 to December 1989

TABLE 2—Interrupted Time Series Analysis for Marriages in Illinois, as well as Bordering and Comparison States

State	ARIMA Trend12	Testing Law[a]	Model LBQ[b]	Model R^2
Illinois	−241	−1043	26	.941
Indiana	−103	457	19	.857
Wisconsin	−43	324	26	.948
Missouri	−88	317	25	.601
Ohio	−49		22	.945
Minnesota	−52		15	.908
Kansas			19	.826

NOTE: Only statistically significant parameter values are presented. All seven states showed significant serial dependency parameters.

[a] Abrupt, permanent change in monthly marriage time series beginning January 1988.

[b] Chi Square test of ACF residuals at 25 lags. None of the reported values are statistically significant, indicating random residuals.

This monthly drop persisted through August 1989. The model indicates that premarital testing reduced the number of marriages in Illinois by 20,860, about 14 percent over the study period.

Crossover Marriages in Border and Comparison States

Table 2 also presents the results of statistical analyses of marriage time series for the three bordering and three comparison states. An hypothesized crossover effect would be revealed by increases in marriages in the border states and no change in marriages in the comparison states.

Inspection of Table 2 reveals that five of the border and comparison states experienced statistically significant year to year (trend) decline in the frequency of marriage. Kansas was an exception. In that state, monthly marriage frequency cycled around a stable average (level) over the entire study period. All six states showed significant moving average components.

Tests of the crossover hypothesis are provided by the Testing Law parameter. In each of the three border states, analysis revealed an abrupt, permanent, and statistically significant increase in marriages in January 1988. Indiana showed a 10 percent increase, Wisconsin a 9 percent increase, and Missouri an 8 percent increase. Together these increases came to an increase of 1,098 marriages per month, starting in January 1988 and lasting through August 1989. The combined increase in these bordering states almost exactly equals the decrease experienced in Illinois.

Of equal importance for testing the hypothesized crossover effect is the finding that none of the comparison states experienced significant changes in marriages in January 1988. The Testing Law parameter was not significant for any of the comparison states although model prediction (R^2) was as good or better for the comparison states as for the border states.

Rebound of Illinois Marriages

The question of a rebound in the Illinois marriage time series with the repeal of mandatory premarital testing cannot be addressed directly with Box-Jenkins times series analysis without a lengthy, post-law time series. An indirect analysis was made by using the intervention model developed in this study to make predictions for the post-law Illinois experience for the last quarter (October–December) of 1989. This model does not include a rebound parameter. Model predictions were compared with the actual number of marriages reported for Illinois during the final quarter of 1989. A rebound would be observed if the actual number of marriages were greater than those predicted by the interruption model. As shown in Table 3, the no rebound model predicts significantly fewer marriages than actually occurred for each of the three months. The interruption model underpredicted the number of marriages in Illinois by an average of 1,100 per month during the period since the HIV testing requirement was repealed. The rebound in marriages in Illinois was approximately equal to the original drop caused by the testing law.

Discussion

The Illinois premarital testing law produced an abrupt decrease in the number of marriages in Illinois. Analyses revealed a drop in the Illinois marriage time series in January 1988 when the law became effective; the drop occurred immediately and lasted throughout the study period. While severe, about 14 percent, the drop was not as great as the 22.5 percent originally reported.[12] There was no statistical evidence that the drop was temporary or that it diminished or increased over time.

Although there was a significant drop in marriages in Illinois, there was not the predicted absolute drop in marriages. Rather than (a) take the HIV blood test and get married in Illinois, or (b) not get married at all, couples crossed the state line and were married in states bordering Illinois. Analyses reveal a coincident, and approximately equal, abrupt increase in the marriage times series for the states most likely to get marriage crossovers from Illinois—Indiana, Wisconsin and Missouri. These increases did not represent a midwestern trend since January 1988 increases were not found for Ohio, Minnesota, or Kansas.

Analysis suggests that the changes in Illinois marriage patterns produced by the HIV testing requirement were not permanent. With the repeal of the HIV testing law, marriages appear to have rebounded in Illinois.

Cost of HIV Testing

Considerable attention focused on the cost of the HIV test itself as a reason for couples' decisions to cross state lines to marry.[9] The media reported charges of up to $400 a couple for HIV tests.[7,18] However, the financial cost of testing may present too easy an explanation. Turnock and Kelly[12] cite a survey of Illinois hospitals with a mean cost of $30 for each HIV test. For half these hospitals, the charge covered both the ELISA and the Western Blot tests. Even a $30 charge may be high since most couples (99.4 percent) would only require the ELISA test.[5] Mercola[19] reports that the cost of the ELISA test to physicians in Illinois was only $10.

Aside from the financial burden, HIV testing did not increase significantly the difficulty of obtaining a marriage license in Illinois. During this period Illinois required a blood test for syphilis, but so did Wisconsin and Indiana. In Illinois, a marriage license was valid the next day, while a three-to-five-day waiting period was required in the three bordering states (see Table 1).

In order for the cost of the HIV test to have produced the marriage patterns revealed in this report, couples must certainly have incurred logistical and financial expenses greater than the cost of two HIV tests. For example, when an Illinois marriage license cost $15 and required HIV tests, more than 6,000 couples chose instead to be married in Wisconsin. There, a marriage license cost $50 with an additional $10 fee for waiving the five-day waiting period, if the Wisconsin county clerk was willing to grant it.[20]

Fear of AIDS

An alternate explanation for the changes in marriage patterns is fear of an AIDS diagnosis.[12,21] Couples may have

TABLE 3—Study Model Predictions for Post-Premarital Testing Marriage Frequencies in Illinois

1989 Month	No-Rebound Model Predictions	Actual Marriages	Residual (under Prediction)
October	8974	9909	(935)
November	6405	7927	(1522)
December	6771	7615	(844)
Mean	7383	8484	(1100)

NOTE: Standard error for predictions is 664. Residuals indicate that actual marriages were higher than expected from the No-Rebound model.

wanted to avoid learning of their (positive) HIV status. Some evidence supporting this explanation is provided for men by the rise in their seroprevalence rates over the testing period. Turnock and Kelly[12] reported male, marriage license applicants' seroprevalence rates of .85 per 10,000 during the first six months of testing. The Illinois Department of Public Health[22] has released figures indicating male seroprevalence rates of 3.23 per 10,000 over the final 14.3 months of mandatory premarital testing. By contrast, the seroprevalence rate for women remained at about 1.4 per 10,000 during the entire period. Male seroprevalence rates show a four-fold increase from the first six months to the final 14 months of testing suggesting that, at least at the beginning of the testing period, men were avoiding marriage in Illinois because of fear of a positive test result.

Although there is evidence that some men got married outside of Illinois to avoid HIV testing, this explanation does not fit with the large change in marriage patterns any better than does explanation in terms of the cost of the HIV test. One expects that only relatively few men had realistic fears of HIV infection. An explanation that is consistent with the fear of an HIV test result is a generalized fear of AIDS. Perhaps AIDS had become such a specter that the issue itself is to be avoided.[23] Couples may have chosen a way around this unhappy topic by being married in a state that allowed them to without testing. ☐

©AMERICAN JOURNAL OF PUBLIC HEALTH May 1991, Volume 81

The *American Journal of Public Health,* published monlthy, is the official Journal of the American Public Health Association. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy.

The Journal, established in 1911, publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Neither the Association nor the Editors assume responsibility for the opinions expressed by authors of papers published or quoted in this Journal. Copyright 1991 by the American Public Health Association, Inc. Second class postage paid at Washington, DC and additional mailing offices.

Subscription price of the *American Journal of Public Health* is $80 per year domestic; $120 per year foreign (air mail); $10 prepaid for single copies of an issue or supplement from the American Public Health Association, 1015 Fifteenth Street, NW, Washington, DC 20005.

I. New York State HIV Seroprevalence Project: Goals, Windows, and Policy Consideration

Lloyd F. Novick, MD, MPH

Introduction

In the summer of 1987, the New York State Department of Health embarked on an extensive effort to determine the prevalence, distribution, and trends of human immunodeficiency virus (HIV) infection in the population. Statewide serosurveillance for antibody to HIV would be conducted by blind testing of available blood samples. Six populations were selected as "windows" on the epidemic: newborns, homeless adolescents, prisoners, and clients of family planning, sexually transmitted disease (STD), and drug treatment clinics. For each of these windows the objectives were to: 1) establish the baseline prevalence and geographic distribution of infection; 2) monitor trends of infection overall and in various populations, including age and racial/ethnic groups; and 3) use the information to target and design preventive activities.

Testing of all newborns in New York State began in November 1987, and all six study windows were operational by June 1988. As of March 1990 blind testing for HIV antibody had been performed on more than 725,000 blood specimens in these six studies. Two years of testing have yielded sufficient data for reliable analysis and projection of trends. The following chapters describe the methods and results of these seroprevalence activities, with emphasis on HIV infection in women of reproductive age, adolescents, and children. HIV seroprevalence rates are correlated with other socioeconomic indicators, including drug-related hospital discharges, the educational level of childbearing women, and the incidence of low birthweights. Information from these surveys has been used to identify high HIV infection rates in small geographic areas and to spur preventive activities statewide.

Impetus for Statewide HIV Serosurveillance

These serosurveillance activities were prompted by two phenomena: the large number of individuals with clinically apparent AIDS in New York State, and the likelihood of a much larger number asymptomatically infected with the virus.

Since the first cases of AIDS were described, New York State has reported more cases than any other state[1] (29,186 by March 31, 1990).[2] Although 84 percent of these cases are residents of New York City, a substantial number (3,564) reside elsewhere in the state. By the same date a total of 18,239 deaths were attributed to AIDS.[2] In New York City, AIDS is the leading cause of death for males 30 to 49 years old, the leading cause of death for females between 20 to 39 years old, and the second leading cause of death for males 20 to 29 years old.[3]

Among children 648 cases of AIDS were reported in New York State as of March 31, 1990.[2] These case reports represent only a fraction of HIV-infected children in New York State, as estimated in the Newborn HIV Seroprevalence Study (see chapter II).

Although case-report data were invaluable in plotting the rise in incidence of AIDS and delineating the associated risk factors, severe deficits in understanding of the epidemic remained. Above all, the current distribution of HIV infection could not be determined from case reports. Most individuals infected with HIV are asymptomatic and not likely to be reported to public health departments, even in states which mandate reporting of HIV infections. (New York State requires reporting of AIDS cases but not HIV infections.) AIDS case reports also lag far behind the prevalence of HIV infection. The median lag time between infection and development of AIDS, resulting in a report to a public health agency, may be 10 years or more.[4]

To determine the actual occurrence of infection, direct and contemporary measures of those infected were needed. The multi-window HIV serosurveillance program could provide such a measure.

A critical need in planning public health interventions was to determine the extent of HIV infection in the entire community and in definable groups and locations. A comprehensive monitoring system, based on a representative, continuing serosurvey, was also needed to track the trends statewide and for age, racial/ethnic, and other groups on a statewide, regional, and community basis.

Approach to Statewide HIV Serosurveillance

The seroprevalence survey method adopted by the New York State Department of Health was blind testing of available blood specimens for antibody to HIV. Representative sampling of households was rejected, although the National Center for Health Statistics and the Centers for Disease Control used this method for a national survey designed to reach 50,000 respondents.[5,6] Seroprevalence analysis of available blood specimens could be implemented faster and more economically than a household survey and would avoid the problems of self-selection and bias associated with community surveys, which require voluntary participation and consent.

Before the Department of Health's blind seroprevalence studies were initiated, extremely limited data were available on the extent of HIV infection in New York State. Seroprevalence information was limited to military recruits and blood donors. Of recruits from New York State 0.35 percent were seropositive, 0.36 percent of males and 0.28 percent of females (Centers for Disease Control: Quarterly Data Report on HIV in Civilian Applicants for Military Service, June 22, 1989). Of 134,144 first-time blood donors seen between July 1987 and September 1988, 0.09 percent were seropositive, 0.12 percent of males and 0.06 percent of females.

The New York State program was based on six major windows, i.e., population groups from whom blood specimens are routinely collected for other purposes. In virtually all cases, sufficient specimen remains for blind assay of antibody to HIV. The six windows are (Table I-1):

Newborns: A dried-blood specimen is routinely collected from every infant born in New York State and screened by the State Department of Health for seven inherited metabolic disorders (see chapter II).

Family planning clients: A number of family planning clinics routinely collect blood specimens for syphilis testing as part of the client's initial medical examination (see chapter VII).

Runaway and homeless adolescents: A shelter for high-risk adolescents in New York City routinely collects blood specimens from individuals referred for medical examination (see chapter IX).

STD clinic clients: Blood is routinely drawn at sexually transmitted disease (STD) clinics for syphilis testing. Twenty clinics outside New York City were recruited in 1987 for the blind HIV study. Results for the fourth quarter of 1989 showed seroprevalence rates of 2.8 percent for 2,792 males and 1.1 percent for 1,318 females. The merged data peaked for clients aged 30–39 (4.3 percent). In the racial/ethnic distribution the rate was higher for Hispanics (3.5 percent) than for Blacks (2.5 percent) or Whites (1.7 percent).[3]

Intravenous drug users (IVDU): Blood is routinely collected from clients being admitted to methadone maintenance programs. Four programs with 35 sites in New York City, including all five boroughs, were recruited for the blind HIV study. Clients entering from June 1988 through December 1989 had very high seroprevalence rates (29.9 percent; males, 31.7 percent; females, 26.6 percent). The rates were high for all age groups, all race/ethnic groups, and all boroughs.[3]

Prisoners: All persons entering the state prison system are processed through central intake facilities, where blood specimens are drawn routinely as part of the medical examination. (For female prisoners, see chapter VI.)

In addition to these six windows, seroprevalance data on two other groups ~~were tapped~~: military recruits and first-time blood donors. Additional data sources have been identified, and the Department of Health is considering incorporation of the data into the survey program.

The Centers for Disease Control developed a similar program in late 1987 to survey HIV seroprevalence for six groups: IVDUs, patients at general hospitals, patients at STD clinics, patients at tuberculosis clinics, patients at clinics serving women of reproductive age, and newborns.[4,5] This Family of Surveys is being conducted in more than 30 areas of the United States. New York is one of the participating states in this surveillance system.

Planning and Policy Issues

Legal Basis—In New York State specimens without identifying information can be used for epidemiologic studies without the need for informed consent. New York State Public Health Law (PHL) Article 24-A regulates research on human subjects and requires informed consent of the subject. However, PHL 2441(2) specifically exempts from the definition of human research "the conduct of biological studies exclusively utilizing tissue or fluids after their removal or withdrawal from a human subject in the course of standard medical practice, or . . . epidemiological investigations." Consequently informed consent of the subjects in the seroprevalence study is not required (memo from Peter J. Millock, General Counsel, New York State Department of Health, to Lloyd Novick, August 24, 1987).

Advisory Committees—An Advisory Committee was assembled on September 17, 1987 by the Department of Health to review the objectives and methods of the proposed seroprevalence surveillance system and the newborn study in particular. The members were Elaine Abrams, MD, Harlem Hospital; Daniel Callahan, PhD, The Hastings Center; Victor DeGruttola, MD, Harvard School of Public Health; Richard Kaslow, MD, National Institute of Allergy and Infectious Diseases; Margarite Pappaioanou, MD, Centers for Disease Control; and Warren Winkelstein, Jr., MD, School of Public Health, University of California, Berkeley.

The Advisory Committee unanimously supported the need for the proposed studies and recommended that data be collected by small area and risk behavior to the extent that anonymity was not compromised. Information on prevalence in areas outside New York City was deemed to be highly important for detecting the extent of spread.

A second special Advisory Committee was convened on March 10, 1988, to review the preliminary results of the newborn serosurvey. In addition to Drs. Abrams and Kaslow, the members were

Table I-1—Windows of the New York State HIV Surveillance Project

Seroprevalence Window	Target Population	Sample	Data Collected	Limitations	Implications
Newborns	Childbearing women 275,000 per annum	All births in NYS 275,000 per annum	Age of mother, race/ethnicity of infant, zip code of hospital	Applicability to reproductive age women	a) Childbearing women b) Women of reproductive age c) Pediatric HIV infection
Family Planning Clinics	Women receiving family planning	41 sentinel family planning clinics 13,000 per annum	Age, race/ethnicity, zip code of family planning center	Sentinels are not representative of all women in family planning	a) Women in family planning b) Women of reproductive age
Homeless Adolescents	Homeless and runaway youth	NYC adolescent facility 12,000 per annum	Age, race/ethnicity, gender, risk	Not representative of the adolescent population	a) Document infection in adolescent groups b) Sentinel population to detect changes over time c) Relationship of risk to prevalence of infection
STD Clinics	Clients at county STD clinics	20 STD clinic sites outside of NYC 5,000 per annum	Age, race/ethnicity, sex, zip code of clinic, syphilis	Representative of only those who go to STD clinics	a) Men and women in STD clinics b) Association of HIV-ab and syphilis c) Spread in women, and, by inference, via heterosexual transmission
IVDU Clinics	All IVDU clients of treatment (methadone)	35 methadone maintenance treatment programs & detox programs in NYC	Age, race/ethnicity sex, treatment modality, drugs injected, sexual orientation, needle sharing, treatment (drug) Hx of HIV-related illness	Clients are in methadone-treatment programs (main drug of abuse = heroin, not cocaine). Not representative of addicts not in treatment	a) IVDU newly entering treatment b) IVDU already in treatment
Prisons	NYS prisoners	Sample of inmates entering at the four intake facilities 500 per annum	Prison site, residence (county), sex, age, race, risk group	Applicability to other populations	a) NYS prisoners b) High-risk population (IVDU), minorities c) Fertility information available

Timothy Dondero, Jr., MD, Centers for Disease Control; Myron Essex, DVM, PhD, Harvard School of Public Health; Harvey Fineberg, MD, Harvard School of Public Health; Margaret Heagarty, MD, Harlem Hospital; Keith Krasinski, MD, Bellevue Hospital; Margaret Oxtoby, MD, Centers for Disease Control; Peter Selwyn, MD, Montefiore Medical Center, and Issac Weisfuse, MD, New York City Department of Health.

This Advisory Committee strongly recommended continuance of the newborn serosurvey, particularly for the purpose of monitoring the epidemic.

Laboratory Facilities—A capability to perform the necessary volume of HIV screening and confirmatory tests was developed at the Department's Wadsworth Center for Laboratories and Research. Automation of the testing process, including employment of robotics, facilitated the implementation of a large seroprevalence study. The Wadsworth Center is now performing nearly 400,000 serologic tests for antibody to HIV annually.

Confidentiality—All laboratory HIV determinations are entered into a computerized data-management system. Names of individuals are not collected, and no identifying information is entered into the data system. Demographic data are collected for all studies (age, sex, race/ethnicity, and zip code), and risk factors are collected for some windows (homeless adolescents, drug treatment clients, and prisoners). To prevent potential identification of any individual from demographic information on a single specimen or a small number of specimens, data are reported only on subgroups that include at least six individuals.

Public Information—Extensive public information was provided about the nature and rationale for this effort before inception of the studies. Information on the newborn study was also provided to hospitals and hospital-based pediatricians. Some public concern was initially expressed about the blind nature of these studies and the inability to notify individuals of their results. To allay this concern, voluntary HIV testing and counseling was offered to individuals in most of the participating facilities.

Ethics—Ethical questions have been raised regarding blind surveys, because positive results indicating infection cannot be linked back to the individual for medical follow-up. Under New York State law individuals cannot be notified of test results from nonidentified (blind) samples obtained without consent. The solution taken by the Department of Health was to offer voluntary testing, wherever feasible, to individuals at the same time as the blind testing. Review of the issues raised by blind testing in a number of reports have emphasized the epidemiologic importance of this type of study and its consistency with ethical practice.[7–9]

Data Limitations and Uses—The limitations of data from blind seroprevalence studies were recognized at the outset. The chief limitation is that the groups available for study are determined by the availability of blood specimens. Some population groups, such as adult males, may be difficult to assess, and the study group is not representative of the entire population. There are also limits on the type of information that can be collected, particularly detailed risk histories.

Despite these limitations the serosurvey results are providing critical data on HIV prevalence in the subgroups tested and on changes over time. The newborn study in particular may have wide applicability to the general population of women of reproductive age in the community, since virtually all childbearing women are participants. Issues of completeness and general applicability of the data are dealt with in later chapters.

Collectively these seroprevalence activities are providing invaluable information on the extent of the HIV epidemic in New York State. Information from these studies has directly influenced the development of preventive actions and public policy.

Summary

In the summer of 1987, the New York State Department of Health embarked on an extensive effort to determine the prevalence of trends of HIV infection in the state. Serosurveillance for antibody to HIV was undertaken by blind testing of available blood samples. Six populations were selected as windows on the epidemic: newborns, homeless adolescents, prisoners, and clients of family planning, STD, and drug treatment clinics. Testing of all newborns in New York State began in December 1987, and all six study windows were operational by June 1988. As of March 1990 blind testing for HIV antibody had been performed on more than 725,000 blood specimens in these six studies. Collectively these seroprevalence activities are providing invaluable information and impetus to preventive actions and public policy. ☐

Donald S. Berns, PhD

Introduction

The New York State Department of Health's ongoing study of HIV infection in childbearing women is based on testing of blood specimens obtained from all infants born in this state for seven inherited metabolic disorders. The specimens are collected and initially tested by the Department's Newborn Screening Program. The specimens are then sent to the HIV Seroprevalence Laboratory for blind HIV testing. This paper describes the results for specimens collected during the 28-month period from November 30, 1987 through March 31, 1990.

Since maternal IgG antibodies cross the placenta, the presence of antibodies in a newborn is indicative of infection in the mother. These antibodies do not necessarily indicate that the child is infected. However, an estimated 30–50 percent of seropositive newborns are actually infected.[1-3]

Methods

Testing Protocol

The protocol for HIV testing of newborn blood specimens has been described in detail by Novick, *et al.*[4] Briefly, a dried-blood specimen is obtained from each infant along with certain demographic information, including the mother's age, zip code and county of residence, the newborn's race/ethnicity, and the month and year of birth. Hospitals are informed of the need for accurate, complete reporting and are contacted, if necessary, to obtain missing information. For the HIV study the demographic information—but not identifying information—is entered into a separate, unlinked data base, where each record is identified by a unique, randomly generated number. The same number is assigned to a portion of the blood specimen. All metabolic disorder screening tests are completed before specimens are submitted for HIV testing.

Specimens for which insufficient or unsuitable blood is left after the metabolic disorder screening are excluded from the blinded HIV seroprevalence study. The number of these specimens is carefully tracked. Repeat specimens cannot be obtained at this stage because the blinding process makes it impossible to link the identity of the infant to the specimen. To ensure that only one specimen representing each childbearing woman is tested, the following are also excluded: all specimens except one from a multiple birth event and all repeat specimens requested for follow-up by the Newborn Screening Program (Figure 1).

Repeat Live Births during Study Period

The likelihood that some women would present with a live birth on more than one occasion during the study period was estimated using Vital Records birth files for 1988 and 1989. Although the Vital Records and HIV newborn data are not directly comparable, this method provides a rough estimate of the percentage of women in the HIV newborn study who had two or more separate live birth deliveries during the study period.

Overall, 3.7 percent of the live-birth records indicated a previous live birth within the same two-year period, 1988–89. However, 29 percent of the New York City records and 11 percent of the remaining records were excluded from this analysis because of incomplete or inaccurate information on the date of the last live birth.

Definition of Test Results

Since the initiation of the Newborn Seroprevalence Study, three sets of crite-

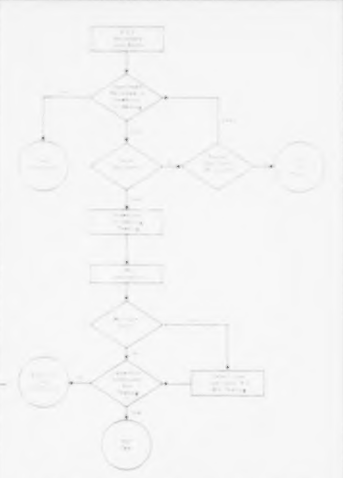

FIGURE 1—New York State Newborn Screening/Newborn HIV Seroprevalence Testing Process

ria have been used to interpret the Western blot results. Reactives were defined as follows:

- Criteria I (November 30, 1987–March 31, 1988): All three of the following: Envelope (gp 41 or gp 120/gp 160), core (p24), and polymerase (p31, p51, or p66).
- Criteria II (April 1, 1988–June 26, 1989): Envelope and either core or polymerase, as defined above.
- Criteria III (June 27, 1989 to present): Any two of the following: p24, gp41, and (gp120 and/or gp160).[5]

Equivocals were defined as virus-specific bands other than the set described above. Nonreactives displayed no virus-specific bands.

Since the individual Western blot band results are currently not available prior to August 1988, the effect of the change from Criteria I to Criteria II could not be examined. However, the change from Criteria II to Criteria III was examined by applying Criteria II to the specimens tested June 27, 1989 to present and comparing the number and percent HIV positive to that found under Criteria III. Under Criteria II there were 1,918 HIV positives with a seroprevalence rate of 0.661 percent. This was nearly identical to that found under Criteria III with 1,921 HIV positives and a seroprevalence rate of 0.662 percent.

Statistical Analysis

Seroprevalence rates were calculated based on the number of Western blot reactives and total specimens tested, excluding equivocals. We could not obtain a second sample for reevaluation of equivocals because of the blinded nature of the study.

Age/race-specific HIV seroprevalence rates were calculated for five racial/ethnic subgroups (White, Black, Hispanic, Other, and Unknown), and six maternal age categories (<20 years, 20–24 years, 25–29 years, 30–34 years, 35+ years and Unknown).

Geographic rates were calculated for New York City total, each of the five New York City boroughs, New York State exclusive of New York City, and four regions outside New York City, which were selected on the basis of urbanization, physical proximity to New York City, and cumulative incidence of AIDS to date. The four regions were New York City Suburban (Nassau, Suffolk, Westchester, and Rockland counties), Mid-Hudson Valley (Dutchess, Putnam, Orange, Sullivan, and Ulster counties), Upstate Urban (Albany, Schenectady, Onondaga, Monroe, and Erie counties), and Upstate Rural (all other counties in the state).

For New York City the HIV seroprevalence rates were also calculated for each zip code area and mapped by quartiles. Zip code areas with fewer than 100 births were eliminated from this mapping. For New York State exclusive of New York City, due to the large number of zip code areas and the small number of births within each area, only the rates for areas with two or more HIV-positive cases and rates twice that of the overall rate were examined, and the rates were mapped by county.

Trend analysis was conducted on the monthly HIV seroprevalence rates for births occurring in the 27-month period, December 1987 through February 1990. Births occurring in November 1987 were excluded from this analysis because the specimens received beginning November 30 covered two-thirds of the November newborns. Plots of the monthly rates were analyzed by simple regression techniques[6–8] with SAS software.[9] A coefficient of determination (R^2) was calculated to determine the proportion of the variation in rates explained by the independent variable, time (month of birth). The 95 percent confidence intervals for the predicted value were also calculated.

This procedure was performed for all of New York State, all of New York City, all of New York State exclusive of New York City, each of the five New York City boroughs, and each of the four other regions described above. The data for all of New York State, all of New York City, and all of New York State exclusive of New York City were further analyzed for three maternal age groups (<20, 20–29, 30+) and for three race/ethnicity groups (White, Black, and Hispanic).

Results

During the study period November 30, 1987 through March 31, 1990, a total of 653,328 blood specimens were analyzed for HIV serologic status, of which 211 equivocals (0.03 percent) were eliminated from the analysis. Of the remaining 653,117 specimens, 10,125 were from women residing outside of New York State, and 2,408 were from women whose residence was unknown. These specimens were also eliminated from the analysis. For the remaining 640,584 specimens, the overall seroprevalence rate was 0.66 percent: 1.24 percent in New York City and 0.17 percent in the rest of the State.

New York City

The HIV seroprevalence rates for New York City and each borough are shown in Table I-1. The rates were highest in the Bronx, followed by Manhattan and then Brooklyn. The rates for Queens and Staten Island were more than twice the rates for the two New York State regions adjacent to New York City, New York City Suburban, and Mid-Hudson Valley.

Of the 170 zip code areas in New York City with 100 or more births, 31 (18.2 percent) had HIV seroprevalence rates in excess of 2 percent and 13 (7.6 percent) had rates in excess of 3 percent. The distribution by quartiles is shown in Figure 2.

The vast majority of HIV seropositives in New York City (89.3 percent) were Black or Hispanic, although only 60.8 percent of newborns were Black or Hispanic.

The highest rates were detected among Black and Hispanic newborns. These rates increased with maternal age for Blacks and Hispanics but not for Whites or Other (Table II-2). The rates for both Black and Hispanic infants peaked in the 30–34 year maternal age group.

Age-specific seroprevalence rates are plotted in Figure 3. The sharpest rise is seen in New York City for infants born to mothers between ages 14 and 24. These rates increased ninefold, from 0.16 percent (1 in 624) for 14-year-olds to 1.41 percent (1 in 71) for 24-year-olds.

TABLE II-1—Percent of HIV Positive Newborns by Region for New York State, November 30, 1987–March 31, 1990

Region	Number Positive	Total Tested	Percent Positive
New York State Exclusive of New York City	601	346,522	0.17
NYC Suburban	329	120,422	0.27
Mid-Hudson Valley	71	29,450	0.24
Upstate Urban	119	88,088	0.14
Upstate Rural	82	108,562	0.08
New York City	3,650	294,062	1.24
Manhattan	799	50,364	1.59
Bronx	998	58,003	1.72
Brooklyn	1,352	104,613	1.29
Queens	424	67,474	0.63
Staten Island	77	13,608	0.57

Women with White seropositive infants were slightly younger (mean 28.6 years) than women with White seronegative infants (29.2 years). Women with Black seropositive infants were significantly older than women with Black seronegative infants (28.2 versus 26.0 years). Women with Hispanic seropositive infants were also significantly older (27.2 versus 25.7 years).

New York State Exclusive of New York City

Seroprevalence rates for New York State and its four regions exclusive of New York City are shown in Table II-1. Rates for two regions adjacent to New York City (New York City Suburban and Mid-Hudson Valley) were only about one-fifth the rate for New York City but twice or three times the rates for the other regions.

HIV seroprevalence was concentrated in certain areas of the state (Figure 4). In New York State exclusive of New York City, 64 zip code areas had two or more seropositives and a HIV seroprevalence rate more than double the average for all areas outside New York City. Of the 64 zip code areas, 50 had rates of 0.5 percent or higher. The 64 zip code areas contained 65 percent of the HIV seropositives but only 16 percent of the newborns tested outside of New York City.

In New York State exclusive of New York City, HIV seroprevalence was highest for Black newborns followed by Hispanics (Table II-3). The majority of HIV seropositives (69.4 percent) were either Black or Hispanic, although only 14.0 percent of the newborns tested were Black or Hispanic. For Black newborns the HIV seroprevalence rate increased with maternal age, peaking in the 35+ age group. For Hispanic newborns the rate increased only in this maternal age group. For White newborns no significant variation with maternal age was found.

As seen in New York City, mothers of White seropositive infants were on average slightly younger than those with White seronegative infants (26.5 years vs 27.7 years); however, the difference is significant in women in New York State exclusive of New York City. Women with Black seropositive infants were significantly older than those with Black seronegative infants (27.7 years vs 24.6 years). Mothers of Hispanic newborns were 1.1 years older (26.5 years vs 25.4 years).

Trend Analysis

When HIV seroprevalence rates were plotted by month of birth for New York City and for New York State exclusive of New York City, with 95 percent confidence intervals, neither slope was significantly different from zero. No significant increase or decrease was found for any borough of New York City, any region outside of New York City, or any three racial/ethnic subgroups in New York State exclusive of New York City.

Only two age groups showed evidence of a statistically significant trend for the 27-month period. For New York City women less than 20 years old (Figure 5A), the rate declined slightly ($y = 0.00785 - 0.000132 \times$, $p < .01$). The standard error of the slope was 0.0000486. However, the coefficient of determination (R^2) was only .23, explaining only a small proportion of the variation in the rate.

For women in New York State exclusive of New York City aged 20–29 (Figure 5B), the rate increased slightly ($y = 0.00149 + 0.00003 \times, p < .03$). The standard error of the slope was 0.0000128. R^2 for this group was extremely small (.17).

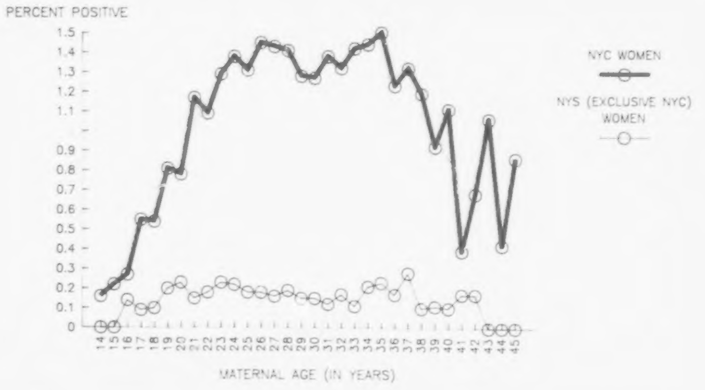

FIGURE 3—HIV Seroprevalence in NYS by Single Year of Maternal Age (November 30, 1987–March 31, 1990)

Discussion

Before this study was implemented, extremely limited information was available on the prevalence of HIV infection in childbearing women. Two recent studies in New York City hospitals revealed an HIV seroprevalence rate of 2.4 to 2.5 percent in infant cord blood specimens.[10,11] A recent Massachusetts Department of Health study found an overall rate of 0.21 percent in anonymously tested newborn blood samples, ranging from 0.1 percent in suburban and rural hospitals to 0.8 percent in inner-city hospitals.[12]

In this study, we found an overall HIV seroprevalence rate of 0.66 percent for childbearing women. The magnitude of this health problem was most striking in New York City where in some zip code areas as many as one out of 22 childbearing women were found to be HIV-infected. For New York State exclusive of New York City the lower overall seroprevalence rate (0.17 percent) is deceptive, because zip code analysis revealed small areas with rates approaching those in New York City. This small-area information is critical for assessment of large geographic areas, where apparently low seroprevalence may mask communities with rates of serious public health concern.

Although 87 percent of the seropositive newborns in New York State were Black or Hispanic, the seroprevalence rate of 0.12 percent for Whites and for other racial/ethnic groups confirms a significant incursion of HIV infection in those populations as well.

The finding of an increased infection rate with increasing maternal age has implications for the design of preventive activities. An especially sharp rise was seen for adolescents and young women in New York City, from 1 in 624 at age 14 to 1 in 71 at age 24 (Figure 3). Preventive efforts must begin with children and younger adolescents to control this rapid spread.

Although racial/ethnic and maternal-age patterns are crucial for projections and resource allocation, the intersection of these patterns offers deeper insight into the environmental factors that determine prevalence. Identifying such cohorts will help to define the relevant exposures, such as patterns of drug use, and thus the targeting of preventive measures. Individuals in younger cohorts with different exposure risks may exhibit substantially different patterns of HIV infection in the future. Those changes will affect not only projections of the epidemic, but also the measures needed to reduce transmission of the virus.

Certain biases inherent in this study may have an impact on the observed rates. Possible bias resulting from newborns not

Tested	29,186	76,996	116,996	87,761	33,764	1,819	346,522

tested is discussed in a later chapter.[13] Another bias could result from double-counting the estimated 3.7 percent of women in the study who may have had two or more separate live birth deliveries within the study period.

Regardless of these biases, data from the seroprevalence study are invaluable in developing estimates of the number of infected women of reproductive age and the number of HIV-infected children. If we assume that 30 percent of seropositive newborns will prove to be infected, 1,275 children with HIV infection were born in New York State during the study period. Yet, only 648 cases of pediatric AIDS had been reported as of March 1990. This gap, attributable mainly to infected but asymptomatic children or those with health problems but no HIV disorder diagnosis, is highly relevant to our understanding of pediatric HIV infection and the need for health care resources.

The few trends found in this study reflect changes in seroprevalence over a brief period of only 27 months. Longer monitoring may be necessary to detect changes in this epidemic. The seroprevalence rates are for a population of childbearing women who have already been infected, plus those infected during the study period, minus those who leave the population by outmigration, death, or aging out of the study. A stable seroprevalence in this limited study may, therefore, be compatible with an actual rising or falling incidence of new infection. The observed trends should also be viewed with caution, because two significant results in 30 separate analyses may be the result of chance alone.

Little information on HIV seroprevalence in newborns is available for the period before late 1987. A rapid increase in HIV infection in childbearing women is assumed to have occurred at some point between 1980 and the present. At the end of 1983, only 174 female AIDS cases had been reported to the New York State AIDS Registry.[14] By the end of March 1990, that number had increased 24-fold to 4,194.[15] The lack of observed trend in the 27-month study period and the increase in infection manifested by AIDS in childbearing women prior to this point suggest a decrease in the rate of increase of the epidemic of HIV infection in childbearing women. However, progress of the epidemic is not likely to be uniform throughout the state with certain lower-prevalence areas possibly exhibiting upward trends in the future.

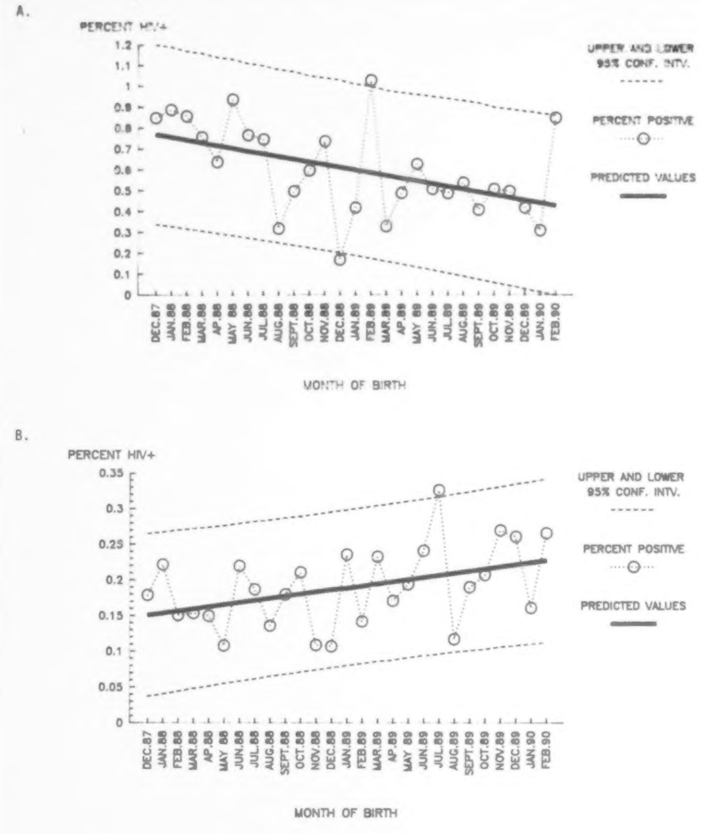

FIGURE 5—Percentage of HIV-Positive Newborns in NYS by Month of Birth for Two Groups with Statistically Significant Trends (December 1987–February 1990)

A—Women less than 20 years old, NYC
B—Women 20–29 years old, NYS exclusive of NYC

Newborn infants of adolescent mothers in New York City showed a decreasing trend in HIV seroprevalence during the 27-month period. This group is particularly critical to the monitoring process as newborns of teenaged mothers have the lowest seroprevalence rates but the greatest rate of increase with maternal age. Seroprevalence among this group may be a closer reflection of recent incidence, since the time interval between HIV infection and childbearing is most likely shorter than that for the older women.

Possible saturation of susceptible individuals in certain geographic areas may also offer an explanation for the lack of observed trends. If so, our efforts toward prevention must be redoubled in these areas, as well as communitywide, to prevent transmission from this pool to others entering various risk groups in the community.

Summary

For the 28-month period, November 30, 1987 through March 31, 1990, 653,117 blood specimens obtained on all newborn infants in New York State for detection of metabolic disorders were also analyzed for HIV serologic status. The overall seroprevalence rate was 0.66 percent: 1.24 percent in New York City and 0.17 percent in New York State exclusive of New York City. Rates of seropositivity were highest in the Bronx (1.72 percent) and Manhattan (1.59 percent). Outside of New York City, HIV seropositivity was concentrated in certain areas. Sixty-four zip codes with two or more seropositives and an HIV seroprevalence rate twice the average outside of New York City contained 65 percent of the HIV seropositives but only 16 percent of the newborns tested. Newborn seropositivity increased with maternal age. In New York City, the seroprevalence rates increased from 0.16 percent (1 in 624) for 14-year-olds to 1.41 percent (1 in 71) for 24-year-olds, a ninefold rise. This survey has provided the impetus for a number of preventive initiatives. ☐

III. Comparison of Newborn Screening Records and Birth Certificates to Estimate Bias in Newborn HIV Serosurveys

Kenneth A. Pass, PhD
Lewis M. Schedlbauer, BA
Patricia A. MacCubbin, MS
Donna M. Glebatis, MS

Introduction

For the New York State Newborn HIV Seroprevalence Study of the magnitude of the HIV epidemic among childbearing women, the completeness and validity of the data as representative of the target population are of prime concern. Missed opportunities for HIV antibody testing fall into three categories:

1. The specimen was not received by the Newborn Screening Program;
2. The initial specimen was invalid or unsuitable for testing and a repeat specimen could not be obtained; or
3. The specimen was insufficient or unsuitable for HIV testing after the mandatory testing was completed.

To assess the potential bias from each of these sources, we determined the number and percent of newborns not tested for HIV antibody within each category and compared the distributions of birth site, residence, race or ethnicity, and birthweight for those not tested and those tested.

Methods

To determine the percent of newborns for which an initial specimen was never received (category 1), live-birth records for 1,000 New York State residents were selected from all 1988 vital records by use of a random sample adequate to yield 95 percent confidence intervals with 1 percent error. These records were computer-matched to newborn screening records; for unmatched records, telephone calls were made to the hospital of birth. The number and percent of live-birth records for which no newborn screening record was available were calculated.

For newborn screening specimens initially invalid with no repeat follow-up specimens and for specimens insufficient or unsuitable for HIV testing, the distributions of birth site, residence, race or ethnicity, and low birthweight (less than 2,500 grams) were compared to the distributions for HIV-tested specimens.

To estimate the minimum impact of the bias, the untested specimens in category 2 (invalid-no repeat) and category 3 (unsuitable/insufficient) were grouped by race or ethnicity and region of birth. The two regions were New York City and New York State exclusive of New York City. The observed HIV seropositivity rate for each race/region subgroup was applied to the number of untested specimens in that subgroup. The overall seropositivity rates were then recalculated with the addition of these results.

To estimate the maximum potential impact of bias from all untested newborn, including those in category 1 (never received), an alternative assumption was made that all those untested were HIV-seropositive. The overall rates were then recalculated.

Results

Specimens Not Tested for HIV Antibody

From the 1,000 randomly selected live-birth records, specimens submitted for newborn screening were matched for 985 newborns. For the remaining 15 birth records two specimens were lost in transit, six were never submitted, and seven represented infants born outside New York State. The parents of these seven infants reside in New York State, but no newborn screening specimen would be expected for an out-of-state birth. Thus eight specimens from an expected 993 (0.82 percent) were not received for newborn screening, but 15 of 1,000 specimens

TABLE III-1—Racial/Ethnic Distribution of Newborns in New York State Tested and Not Tested* for HIV by Region of Birth

NYS = New York State

(1.5 percent) for infants born to New York State residents were not received for HIV testing.

Of the 281,921 initial specimens received in 1988, a total of 275,630 were tested for HIV, while 1,558 (0.5 percent) were invalid and no repeat specimen could be obtained. An additional 4,733 (1.7 percent) specimens had an insufficient quantity left over after mandatory testing or were unsuitable for HIV testing. If the total number of specimens received was increased by 1.5 percent to reflect the estimated number of specimens never received, the expected total of HIV specimens would be 286,150. Of these, 275,630 were actually tested, leaving an estimated 10,520 newborns (3.7 percent) not tested.

Marked differences were found among hospitals in the percentage of newborns not tested (data not shown). Thus the seroprevalence rates were impacted by factors other than the biological transfer from mother to child.

Comparison of HIV-Tested and Not Tested Newborns

For category 2 (invalid-no repeat) and category 3 (specimen insufficient or unsuitable) considered together, 54 percent of untested and 45 percent of tested newborns were from New York City. More untested than tested newborns were associated with an unknown or out-of-state residence (6 percent and 2 percent, respectively).

The racial/ethnic distributions of HIV-tested and not tested newborns by region are presented in Table III-1. In both New York City and New York State exclusive of New York City the untested groups had a higher percentage of Blacks.

Category 2 (invalid specimens with no repeat specimens obtained) had a disproportionate share of specimens at lower birthweight (13 percent, compared to only 9 percent of all specimens received). Birthweight information was not available for 6 percent of the invalid-no repeat group and for only 2 percent of all specimens.

Estimation of Potential Bias

If the assumption is made that untested specimens in categories 2 and 3 had HIV seroprevalence rates equal to those observed for their race/region subgroup, the number of additional HIV-seropositive infants expected would be 54 (Table III-2). Including these untested newborns would increase the overall seroprevalence rate from 0.642 (1,770/275,630) to 0.647 (1,824/281,921).

The estimated number of all newborns not tested for HIV (including category 1) in 1988 is 10,520. Assuming all 10,520 to be seropositive and including them in the calculation would increase the overall seroprevalence rate nearly sevenfold, from 0.64 percent to 4.29 percent.

Discussion

Since our newborn screening program is designed to test all infants born in New York State, use of the dried blood spots for HIV seroprevalence testing ensures that there is no predetermined bias. However, bias may exist due to biologic factors, such as the mother's health or exacerbating medical conditions of the child. This bias may be particularly important in areas with low seroprevalence rates, where a systematic error could distort the calculations.

The results reported here indicate that the seroprevalence study was able to determine the HIV serostatus of all but 3.7 percent of the childbearing women in the state in 1988. Although the proportion not tested is relatively small, it could still be an

important factor if the characteristics of the untested newborns are similar to those population subgroups with high HIV seroprevalence.

Our study indicated that bias may exist from the untested newborns because their racial/ethnic, regional, and birthweight distributions differed from those tested. If these untested newborns were all seropositive, the seroprevalence rate would be increased nearly sevenfold. This is the maximum bias in these data. The bias of 0.005, calculated by applying the existing seroprevalence rates to specimens in categories 2 and 3, is doubtless unrealistically low. The true bias lies somewhere in between.

Initiation of testing newborns for HIV status has focused additional attention on the quality of specimens and completeness of data submitted to the Newborn Screening Program. Several improvements have been observed. At the beginning of the seroprevalence study 12 percent of the specimens submitted were missing key information such as mother's age, county of residence, and ethnicity. Hospitals were called to secure the information. Within four months less than 3 percent of the specimens were submitted with information missing. Similarly, the quality of blood specimens increased due to focused efforts of laboratory staff in dealing with problem facilities.

Summary

Implicit in the New York State Newborn HIV Seroprevalence Study is the assumption that newborns of all New York State residents are tested for human immunodeficiency virus (HIV) antibodies. We examined this assumption by describing that part of the 1988 New York newborn population not tested in the HIV seroprevalence study and assessing any bias contributed by this group. Of the expected total HIV specimens 1.5 percent were never received by the Newborn Screening Program, 0.5 percent were invalid specimens for which no repeat specimen could be obtained, and 1.7 percent were unsuitable or of insufficient quantity to be tested for HIV antibody. Thus 96.3 percent of all 1988 New York newborns were tested for HIV antibody. Black infants from New York City and low-birthweight infants were represented disproportionately among those not tested. Assignment of all untested newborn to HIV-positive status increased the seroprevalence rate 17 percent (0.64 percent to 0.75 percent). ☐

IV. Geographic Distribution of Newborn HIV Seroprevalence in Relation to Four Sociodemographic Variables

Dale L. Morse, MD, MS
Lawrence Lessner, PhD, MPH
Michael G. Medvesky, MPH
Donna M. Glebatis, MS
Lloyd F. Novick, MD, MPH

Introduction

Since the AIDS epidemic was first recognized, there has been geographic clustering of AIDS cases within the United States and New York State. Most of this clustering is related to pools of HIV-infected individuals and to risk behavior activities which occur most frequently in metropolitan areas and states with large populations at risk. Witness the high rates of AIDS cases among homosexual and bisexual men in New York City and San Francisco and among intravenous drug users in urban areas of New York, New Jersey, and Florida.[1,2] In an earlier study in New York City, zip code areas with rates of drug-related hospital discharges in the top quartile had a newborn HIV seroprevalence of 2.2 percent versus 0.8 percent in all other zip code areas.[3]

Identification of geographic clusters of cases can be useful in focusing preventive efforts and allocation of health care resources. HIV/AIDS cases are also likely to be closely clustered in association with other sociodemographic variables. Knowledge of such relationships could be useful for targeting and design of prevention services which would differ between high-risk areas and areas where HIV/AIDS has not yet surfaced.

This report summarizes data on the geographic distribution of HIV seroprevalence among New York State newborns and its association with four sociodemographic variables: birthweight, maternal education, race/ethnicity, and drug abuse leading to hospitalization. Although such associations do not indicate causation, they provide insights for further investigation.

Methods

Three sources of data were used: the New York State Newborn HIV Seroprevalence Study, the Birth Certificate Registry, and the New York State hospital discharge file. The data variables analyzed included newborn HIV seroprevalence;[3] hospital discharges with opioid, cocaine, and infant drug withdrawal diagnoses; birthweight; maternal education; and race/ethnicity. All results were converted to rates or percents by zip code, using 1988 postal zip codes.[4]

Newborn HIV seroprevalence and race/ethnicity data included all newborns born after December 31, 1987 and tested for HIV between January 1, 1988 and August 31, 1989. Rates for these variables were calculated as percentages of the total number of newborns tested.

Opioid, cocaine, and infant drug withdrawal diagnoses were obtained from the Statewide Planning and Research Cooperative System for 1988[5] by using the International Classification of Diseases—Ninth Revision codes (304.0, 304.7 and 305.5 for opioid; 304.2 and 305.6 for cocaine; 779.5 and 760.72 for infant drug withdrawal). A combined all-drug variable was established by combining all such adult discharges. Rates per 100,000 population were determined by using zip codes of residence for all persons discharged and zip code population data from the 1985 National Planning Data Corporation estimates.[6] For the infant drug withdrawal rate the denominator was the number of newborn discharges per zip code.

Data on low birthweight (defined as less than 2,500 grams) and low maternal education (defined as fewer than 12 years) were obtained from the registry of 1987 birth certificates.

Geographic comparisons at zip code level were made separately for New York City and for New York State exclusive of New York City. Zip code areas were excluded from the statistical analysis if they had fewer than 100 births, absent variables, or extreme values which were outliers. All variables were mapped by quar-

tiles for visual ecologic comparison. The geographic distribution of newborn HIV seroprevalence was compared to that of each sociodemographic variable by using Pearson correlation coefficients and multiple regression.

Results

Ecologic Mapping

Visual review of maps of newborn HIV seroprevalence rates by zip code area showed clustering in both New York City (Figure 1) and New York State exclusive of New York City. For New York City all maps of individual drug variables showed a similar pattern so only the most significant variable, all drugs, is presented here. Maps for New York State excluding New York City are not displayed, because release of such data from zip code areas with small numbers could compromise confidentiality.

The first and second quartiles for HIV seroprevalence in New York City had rates of 1.6 to 6.1 percent and 0.7 to 1.5 percent, respectively. The sociodemographic variables were also clustered but appeared to be more closely associated with HIV seroprevalence in New York City than in New York State exclusive of New York City.

Statistical Analysis: New York City

Of the 348 New York City zip code areas listed for 1988, 326 had valid entries listed, but 151 had no population and were excluded, leaving 175. All but five of these areas had a population of 3,798 or more. This restricted file contained 99.5 percent of all births, 99.8 percent of all HIV seropositives, and 99.7 percent of all drug discharges. Further exclusion of nine areas with fewer than 100 births and one area with an extreme drug discharge rate left 165 areas on which the analysis was done. These restrictions entailed minimal loss of data for the variables under consideration (Table IV-1). Over 98 percent of the information for each variable was included in the restricted data set for correlation and regression analyses.

Univariate correlation analysis showed HIV to be correlated in varying degrees with all sociodemographic variables studied in New York City (Table IV-2). Most variables were also highly correlated with one another. If one controlled for low birthweight and the various drug variables in calculating Pearson partial correlation coefficients, low maternal education, percent Black, and percent Hispanic were no longer significantly correlated with HIV. The drug variables were

Infant Drug Discharges	363	40	323	11.0%

*See Text

all highly correlated with one another. A model comprising low birthweight and all drug discharges was shown by multiple regression analysis to be the best predictor of HIV status ($r^2 = .77$). Addition of all remaining variables added little to the model. Low birthweight by itself contributed most to the model ($r^2 = .69$; data available on request).

Statistical Analysis: New York State Exclusive of New York City

Of the 1,918 zip codes listed for New York State exclusive of New York City in 1988, 1,884 had valid entries, but 354 had no population and were excluded. For the remaining 1,530 the median population was 2,441, and 25 percent had populations less than 1,000. This restricted file contained 98.9 percent of all births, 99.2 percent of all HIV seropositives, and 99.2 percent of all drug discharges. Because of small denominators, however, many areas had several extreme or missing values, leading to exclusion of 1,013 areas (1,006 with fewer than 100 births and seven as outliers). These exclusions left only 517 areas for the correlation and regression analyses and resulted in loss of data for a number of variables (Table IV-1). Overall 82 percent of the population, 88 percent of births, 86.4 percent of newborn HIV seropositives, and 83.2 percent of all drug discharges were included in the restricted data set.

Univariate correlation analysis on this restricted data set showed HIV to be less strongly correlated with all variables than in New York City. The variables with the highest correlation were percent Black, percent Hispanic, and the drug variables (Table IV-2). A model comprising percent Black, percent Hispanic, and cocaine drug discharges was shown by multiple regression analysis to be the best predictor of HIV status ($r^2 = .39$). Addition of all remaining variables added little to the model ($r^2 = .43$). The two race variables contributed most to the model ($r^2 = .36$), but all variables were closely associated, and a model without race/ethnicity was almost as good ($r^2 = .42$).

Discussion

The variables used for the analysis were chosen because of their availability, completeness, and suitability as measures of sociodemographic status. Low birthweight has been associated with socioeconomic status.[7] Maternal education, available on the birth certificate, had been demonstrated as a good surrogate for maternal socioeconomic status in previous Departmental studies.[8] Drug discharges, while not a measure of the total drug problem, reflect its distribution by providing a measure of one of its severe outcomes (hospitalization).

Other variables were considered but rejected for one reason or another. For example, sexually transmitted disease rates were not always available by zip code, and Medicaid participation is a biased measure of socioeconomic status because of wide differences in enrollment by locality.

Zip code was chosen as the geographic level of analysis because prevention activities must be targeted to small geographic areas and because a dilutional effect is seen when larger units, such as counties, are used.

Most pediatric AIDS cases are associated with use of intravenous drugs by one or both parents.[1] Of the 590 pediatric cases reported in New York State through October 1989, 346 (59 percent) had mothers who used intravenous drugs, and 108 (18 percent) had mothers who were sexual partners of intravenous drug users.[9] The associations between newborn HIV seroprevalence and hospital intravenous drug discharges in the present study were therefore expected. The high correlation with cocaine discharges, however, is of particular concern. While these mothers may have also used intravenous drugs, the cocaine association could reflect an increased heterosexual transmission of HIV, given the marked increase in syphilis transmission associated with sex in exchange for crack cocaine.[10]

Low birthweight is associated with inadequate health care, poor nutritional status, low socioeconomic status, low level of maternal education, and alcohol and other substance abuse,[7,11-13] including use of cocaine and heroin.[14-16] Thus it was not surprising to find low birthweight closely correlated with newborn seropositivity in New York City. Although drug use, as measured by hospital discharges, added to the association, its contribution was less than that of low birthweight. Hospitalization for drug use measures only the more severe portion of a locality's drug problem. Low birthweight may be a better reflection of the problem for the total community. Theoretically low birthweight could be an outcome of, rather than a surrogate for, HIV seropositivity. However, several studies have shown that there are no significant differences in birthweight between

newborns of HIV-positive versus HIV-negative women when the analysis controls for drug use and socioeconomic status.[17-19]

Race/ethnicity was correlated with HIV seroprevalence in New York City, but this correlation appeared to be related primarily to low birthweight and drug use. This finding parallels AIDS case rates, where minorities have much higher case rates but primarily as a function of intravenous drug use.[20]

A different pattern of correlations was seen in New York State exclusive of New York City. The geographic distributions of all sociodemographic variables were still correlated with newborn HIV seroprevalence by zip code, but the correlation coefficients were far less strong. Also, on multiple regression analysis, race/ethnicity replaced low birthweight as the most significant, albeit minimal, predictor of HIV status, while drug use remained a contributor.

Minorities have previously been shown to be disproportionately affected by AIDS, with case rates three to 12 times those of Whites.[21] Blacks and Hispanics contribute 24 percent and 14 percent of the United States AIDS cases, respectively, while comprising only 12 percent and 7 percent of the population.[22] Among AIDS patients, 71 percent of all women are Black or Hispanic, as are 77 percent of all children.[1] These differences have been repeatedly associated with intravenous drug use and secondary heterosexual and perinatal transmission.[20-23]

The reason why race/ethnicity appears to be a better correlate for HIV than low birthweight or drug use in New York State exclusive of New York City is unclear. Some possible explanations are the smaller amount of data available for analysis by zip code, the lower prevalence of drug use resulting in hospitalization (drug discharges per 100,000 population were 17 percent of those in New York City), and the lower rate of newborn HIV seroprevalence (0.16 versus 1.25 percent). Furthermore, the ratios of AIDS case rates for Blacks and Hispanics compared to Whites have been much greater in New York State exclusive of New York City (7.6 and 5.2, respectively, versus 2.1 and 2.0). Similarly, the ratios of HIV newborn seroprevalence rates for Blacks and Hispanics are 15 and 10 times higher, respectively, than for Whites in New York State exclusive of New York City, compared to six and four times higher in New York City.

While the major emphasis for public health HIV/AIDS programs has been on universal education and precautions, efforts targeted at high-risk persons or geographic areas are also important. Our results confirm that prevention activities in New York City should be focused on geographic areas that have low HIV/AIDS rates but populations with low birthweights and high drug use—that is, populations at risk for future HIV/AIDS activity—as well as on geographic areas with already high HIV/AIDS rates. The extent to which sociodemographic factors are important predictors outside New York City remains to be seen.

Summary

The geographic distribution of newborn human immunodeficiency virus seroprevalence at zip code level was compared with the distribution of four sociodemographic variables. For New York City significant univariate correlations were found between HIV and low birthweight, drug use (as measured by hospital discharges), maternal education less than 12 years, and race/ethnicity. Less significant correlations were found for New York State exclusive of New York City. For New York City a model comprising low birthweight and all drug discharges was shown by multiple regression analysis to be most strongly associated with HIV status ($r^2 = .77$). Elsewhere a model comprising race/ethnicity (percent Black, percent Hispanic) and cocaine

drug discharges had the best, but less strong association ($r^2 = .39$). However, because of intercorrelations, race/ethnicity added little when the other variables were included first. Knowledge of the geographic association between HIV seroprevalence and sociodemographic status can be useful in designing and focusing prevention efforts in areas at highest risk for future HIV/AIDS activity. ☐

V. Projection of AIDS Incidence in Women in New York State

Lawrence Lessner, PhD, MPH

Introduction

One objective of the New York State Newborn HIV Seroprevalence Study was to provide information for AIDS case projections. Earlier projections were developed by linear extrapolation from reported AIDS cases. The limitations of using AIDS case reports include underreporting of AIDS cases, reporting delays, and, most importantly, the long incubation period of HIV infection.

To improve the projection process, we turned to data from two other sources: fertility data, and the results of the Newborn HIV Seroprevalence Study. With these and other data, we estimated the number of HIV-infected women of reproductive age in 1988 and then the number of women infected each year during 1981–88. From this distribution of the incidence of infection and an incubation distribution, we projected the anticipated AIDS case incidence for this population.

The AIDS case projection methods developed here are a form of back calculation.[1,2] The major advantage of this application is that information from another data source, newborn HIV seroprevalence, is employed to obtain an estimate of the number of infected women of childbearing age in 1988.

As newborn serosurveys for antibody to HIV are implemented in more states, this type of analysis will become increasingly important in efforts to anticipate future AIDS cases.

Methods

AIDS case projections were developed in three steps:

1. Newborn seroprevalence results from 1988 provided an estimate of the number of infected women of reproductive age in 1988.

2. An incubation distribution was used to create an expected case series for each number of a family of hypothetical distributions of incident infections. A "best distribution" of infections was selected by comparing the expected and actual case series.

3. A lower bound on future AIDS cases for this population was obtained from the estimates of presently infected women.

Estimating the Number of Infected Women

The number of HIV-seropositive newborns in 1988 was obtained from the Newborn HIV Seroprevalence Study[3] for each of 80 age, racial/ethnic, and geographic strata. The number of HIV-infected women of reproductive age (15–44 years) in each stratum was determined by dividing the number of newborn HIV seropositives[3] by the fertility rate for that stratum. The total estimate is the sum of these 80 stratum-specific estimates.

The fertility rate R of a given female population is defined as B, the number of live births that occur in the population during the given year, divided by P, the average or midyear population for the given female subgroup of age 15 to 44 years: R = B/P. An estimate of P_i, the size of the infected female population, was obtained by inverting the relationship: $R_i = B_i/P_i$. If B_i is the number of seropositive births and R_i is the fertility rate in the infected female population, the population size is $P_i = B_i/R_i$. Assuming the same fertility rate for infected women as for the entire stratum $R_i = R$, then $P_i = B_i/R$.

Since the fertility rate R varies by age, race, and geographic location, the population was stratified by age (15–19, 20–29, 30–39, 40–44 years), race (Hispanic, non-Hispanic Black, non-Hispanic White, and all others), and five geographic regions: New York City (the five bor-

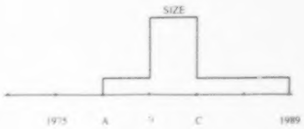
FIGURE 1—Procedure for Estimating the Total Number of Women Infected During 1981–88



A The beginning of the infection epidemic curve, called START, has values 1975, 76, 77, 78, 79, 80

B Called CENTER, is the beginning of the period of high injection activity and has values 1975 to 1980 and is constrained by A≤B

B.C The interval from B to C is called the period of high infection activity, has length C - B = WIDE, has values 1, 2, 3, 4 years

SIZE Is the proportion of cases in the period of high infection activity, has values .5, .6, .7, .8, and .9

FIGURE 2—Generic Candidate For Distribution of Infections

oughs); New York City Vicinity (Nassau, Suffolk, and Westchester Counties), Mid-Hudson Valley (Dutchess, Orange, Putnam, Rockland, Sullivan, and Ulster Counties), Upstate Urban (Albany, Schenectady, Onondaga, Erie, and Monroe Counties), and Upstate Rural (all other counties).

Vital statistics data for 1980 and 1988 were used to obtain estimated stratum-specific fertility rates. The 1980 fertility rates were increased in each stratum to reflect the 1988 fertility experience: ages 15–19 were increased by 17.8 percent, ages 20–29 by 4.1 percent, ages 30–39 by 30.5, and ages 40–44 by 48.9 percent (J. Cooney, Bureau of Production Systems Management, New York State Department of Health, oral communication, January 1990).

The model for estimating the number of women infected during 1981–88 is presented in Figure 1. This tree diagram partitions the ever-infected population into disjoint subgroups for which infection is estimated. Subgroups 4 and 6 use estimates from the AIDS Reporting System (ARS) which is considered 80 to 90 percent complete (Dr. Meade Morgan, Chief of Statistical and Data Management Branch, Division of HIV/AIDS, Centers for Disease Control, oral communication, January 19, 1990).

Estimating the Distribution of Infections

A family of candidate distributions was examined for their utility in describing the incidence of HIV infection in women during 1981–88. The generic candidate (Figure 2), a two-step histogram, was generated by specifying four parameters: START, WIDE, CENTER, and SIZE. START, the beginning of the infection epidemic, had possible values 1975, 1976, . . ., 1980. The interval of high infection activity begins at CENTER and had possible values that range from START to 1988. WIDE is the width of the period of high infection activity and had possible values 1, 2, 3, or 4 years. SIZE is the proportion of infections within the period of intense infection activity and had possible values 0.5, 0.6, 0.7, 0.8 or 0.9. With this model there are 1,200 possible two-step histograms.

A Weibull incubation distribution was selected with a median of 10 years and a fifth percentile of 3.5 years. This selection was based on reports of incubation distributions in a hemophiliac population and in the San Francisco Gay Cohort,[4,5] with estimated median incubation times of 10.0 and 9.8 years, respectively. The estimated fifth percentiles of incubation times were 3.6 and 3.4 years, respectively. An expected case series was created for each of the 1,200 candidates and compared to the annual observed, lag-adjusted AIDS case incidence.

The comparison measure, called ERROR, is the sum of the absolute differences between the observed and expected incidences for each year in each candidate series. The 1,200 ERROR sums were ordered from smallest to largest. Absolute accuracy was measured by ERROR. Relative accuracy was obtained with %ERROR, which is ERROR divided by 2,589, the total incidence observed during 1981–88.

To validate the use of an incubation distribution with a median of 10 years and a fifth percentile of 3.5 years, a family of nine Weibull incubation distributions was created having a 50th percentile of 9, 10, or 11 years and a 5th percentile of 3.0, 3.5 or 4.0 years. Each of these incubation distributions and each of the 1,200 histograms of infection were combined to produce 10,800 candidates, and for each candidate an expected case series was calculated. The top 50 candidates, as ranked by ERROR, were examined to find the smallest ERROR for each incubation distribution (Table V-1). This calculation was at least consistent with the choice of 10 and 3.5 years, although the choices (10, 4.0) and (9, 4.0) appeared equally good. The choices where the 50th percentile is 11 or the 5th percentile is 3.0 appeared considerably less consistent with the observed case series.

Projections of AIDS Case Incidence in Women

The candidate with the minimum value of ERROR was selected as the estimate of the distribution of infections. The expected number of cases was calculated for each year as a lower bound on the anticipated future incidence of AIDS cases in women.

TABLE V-2—Summing the Decision Tree (Figure 1)

Box	Population (Origin of the estimate)	The Estimate
1	Women of childbearing age in 1988 (Inverting the fertility rates over 80 strata)	23,430
2	Alive in 1988 and age 45 or more, but not an AIDS case by Dec. 1988 (Unknown)	No estimate
3	An AIDS case in ARS by Dec. 1988 (ARS)	297
4	An AIDS case by Dec. 1988 but not in ARS (10% of 297)	30
5	AIDS case in ARS and dead by 1987 (ARS)	1,308
6	Dead AIDS case by Dec. 1987 and *not* in ARS (10% of 1,308)	131
7	Not AIDS case and died from either other causes or HIV-related disease not AIDS (Unknown)	No estimate
Total		25,196

Results

Estimates of Number of Infected Women (15–44 years)

If we assume equal fertility rates for the general and infected populations in each of 80 age, racial/ethnic, and geographic strata, an estimated total of 23,430 women age 15–44 years were infected with HIV in New York State in 1988. This total was used to obtain an estimate of all women infected during 1981–88 (Figure 1, Table V-2).

Estimates were not possible for certain populations. Box 2 represents all women infected during this period who were alive and age 45 years or more in 1988 but who were not a defined Centers for Disease Control (CDC) case by December 1988. This is the only source of infected women who are potential future AIDS cases for which there is no estimate. Box 7 represents all women infected during this period who died by December 1987 from causes not related to HIV infection. This population will not influence future AIDS incidence.

The estimate of all HIV-infected women of reproductive age in New York State during 1981–88 is 25,196.

Estimates of Distribution of Infections during 1981–88

The 1,200 candidates were ordered by increasing values of ERROR, and the observed and expected cases for six representative candidates were compared (Table V-3). The best candidate had half the ERROR of the next-best candidate.

Three populations of candidates for the infection distribution—the best 10, 20, and 30 candidates—were examined for consensus on the four parameters (Table V-4). START had a clear single mode across all three populations. This is a strong consensus that year 1980 was the beginning of the infection distribution. For CENTER there was a strong consensus across all three populations for 1984 and 1985.

The consensus for the percentiles (Table V-5) shows that the cumulative proportion of new infections nearly doubles in 1984 for each of the three populations. Thus the period of intense infection activity began in 1984. The three-year period 1984–86 accounts for 70 to 80 percent of all infections.

Projections of Future AIDS Cases

The three best candidates for the distribution of infections were used with the incubation distribution to project future AIDS case incidence for 1989 to 1993 (Table V-6). A considerable consensus was found for each year across the three best candidates, and the means and standard deviations for the top 20 candidates substantiated this consensus. The average observed coefficient of variation for these five years was 0.0313. The best candidate indicates that if there were no additional infections after December 1988, the minimum cumulative number of cases expected December 1993 is 8,295.

The linear projections in Table 6 are estimates of future AIDS incidence calculated from actual monthly AIDS surveillance data by linear extrapolation.[6] These linear projections and the best candidate show considerable similarity for the first three years. Beginning in 1992 there is a growing divergence. The linear projections continue to increase each year by a fixed amount, 277 cases. The rate of increase in the candidates is governed by the distribution of infections and, in time, if one assumes no additional infections, there will be a slowing in the rate. Since these projections make no attempt to anticipate future infections, they must be viewed as a conservative estimate.

Discussion

These projections of future AIDS cases among women of reproductive age are based on the results of a newborn HIV seroprevalence study in New York State. An earlier method, linear extrapolation, yielded similar projections for the short term.[6] Projections by extrapolation will always exceed those produced with a method that uses a fixed number of infected because the projections of AIDS cases produced here are based only upon presently infected persons; they must be considered a lower bound of expected cases.

Back calculation is a general class of methods that uses an incubation distribution and the observed case incidence series to estimate the distribution of infections over time.[1,2] The method discussed here, employing two-step histogram, suffers from all the usual disadvantages of back-calculation methods: underreporting of case incidence, limited knowledge of the incubation distribution, and absence of case reports before a certain year (in this case 1981). The key theoretical advantage of back calculation, compared to earlier empiric extrapolation, is its direct quantification of the size of a previously infected population.

The potential limitations of the validity of the work presented here include the assumption of equal fertility between the general and the infected populations in each stratum, the selection of an incubation distribution, the simplicity of the two-

step histograms, and the underrepresentation of infections occurring during the survey period, 1988.

A fundamental assumption in relating newborn seropositivity to infections in all women of reproductive age is that HIV-infected women have the same fertility rate as uninfected women in the same age, racial/ethnic, and geographic strata. However, the possible effects of HIV infection challenge this assumption. Intravenous drug use could also reduce fertility and thus low-bias the estimate of infected women of childbearing years.

Few published reports address the potential differences in fertility between the general population and HIV-infected or intravenous-drug-using women. Commonly the comparison is between seropositive and seronegative women who are also or have been intravenous drug users.[7-10] For these groups no differences in fertility have been observed.

If there is a decrease in fertility in HIV-infected women, it may be secondary to associated intravenous drug use. Selwyn[7] compared the pregnancy rate of women in the Bronx in 1985 with a cohort of intravenous drug users enrolled in a methadone maintenance treatment program. The latter group had an estimated decrease in the fertility rate of 4.7 pregnancies per 100 person-years. Thus if there is a decrease in fertility, it is likely to be small (Dr. Peter Selwyn, Department of Epidemiology and Social Medicine, Montefiore Medical Center, New York, NY, oral communication, January 1990).

To investigate the sensitivity of the assumption of equal fertility, we computed the estimate of total infected women for progressively decreasing fertility rates in the infected population. If

$$\sum_{i=1}^{80} \frac{B_i}{R_i}$$

is the original estimate of the total number of infected women of childbearing age in 1988,

$$\sum_{i=1}^{80} \left[\frac{B_i}{(1-a)R_i} \right] = \left[\frac{1}{1-a} \right] \sum_{i=1}^{80} \frac{B_i}{R_i}$$

is the estimate resulting from a 100a percent decrease in fertility. The results of these calculations are given in Table V-7, as well as the ERROR for the best, the best five, and the best 10 candidates for each scenario of decreased fertility. These ERROR values measure the consistency of the assumed decrease in fertility.

As fertility decreases, the estimated total number of infected women increases to 48,626 (corresponding to a 50 percent decrease in fertility). The three ERROR values generally increase with decreases in fertility. This generally increasing ERROR implies a degradation in the consistency of the model and casts doubt on the estimated total number of infected women that results from a severe decrease in fertility. Modest decreases in fertility result in larger but still credible estimates of infecteds (a 15 percent decrease in fertility results in a 16 percent increase in infecteds and a 13 percent increase in best-10 ERROR). Larger decreases in fertility are clearly much less credible than the estimate of no difference in fertility rates between the HIV-infecteds and the general population.

The selection of the incubation distribution was based upon two articles[4,5] that indicated consensus in the choice of a Weibull distribution and its parameters.

NOTE: The average cumulative number of new infections from 1975 to the given year for the Best 10, 20 and 30 Candidates is shown. The standard deviation for the data is given in parentheses

Attempts at verification were consistent with those reported in both articles.

Although structurally more complex histograms would yield more accurate results, our simple histograms still offer a wide variety of choices. In any case, parametric modelers performing a back calculation with maximum likelihood methods must necessarily limit the form of their candidate populations for each estimate.[2] The accuracy of the expected case series in the best several candidates (Table V-3), the strength of consensus in parameter estimates (Table V-4), and the strength of consensus in the future num-

bers (Table V-6) confirm the adequacy of the simple histograms.

This method, utilizing HIV seroprevalence data from newborns, has resulted in improved projections of AIDS case incidence in women and may be useful in developing improved projections of pediatric AIDS.

Summary

The results of the Newborn HIV Seroprevalence Study in New York State for 1988 were used to estimate the number of human immunodeficiency virus (HIV)-infected women of childbearing age in 1988. The estimate was accomplished for each of 80 age, racial/ethnic, and geographic strata by dividing the number of seropositive newborns by the 1988 estimated fertility rate. Summing across strata yielded a total of 23,430 infected women age 15 to 44 years in 1988. From this estimate a tree model was used to estimate the number of women infected during 1981–88. Back calculation was used to distribute these infections over time, and the selected incubation distribution was used to estimate future AIDS cases for this population: 8,295 cases by 1993. □

Introduction

Human immunodeficiency virus (HIV) infection is becoming a leading medical problem among prison inmates in the United States, especially in states where the infection is prevalent. By October 1988 a total of 3,136 AIDS cases had been reported among inmates in a survey of 70 federal, state, and local correctional systems.[1] In New York State, which has more AIDS cases than any other state,[2] 1,046 cases had been reported among inmates of the state system by September 30, 1989.[3]

Because of the continuous turnover of prisoners, it is difficult to determine the precise number of persons with AIDS in New York State prisons at any time. However, a survey by the New York State Department of Correctional Services estimated that in September 1989 there were more than 800 inmates with symptomatic HIV disease and that approximately 550 inmates were on zidovudine therapy (Dr. Robert Greifinger, New York State Department of Correctional Services, personal communication). AIDS and HIV-related illness became the leading causes of death among inmates in 1985 and accounted for 68 percent of inmate deaths in 1987.[4]

In addition to severe HIV disease, there is evidence that many New York inmates are asymptomatically infected with HIV. A 1987 study of men entering the main intake center found that 17.4 percent were HIV-seropositive, the highest rate reported in any blind seroprevalence study of prisoners.[1,5] For intravenous drug users the rate was 44 percent. This study suggested that approximately 2,200 of the 12,600 men who entered this center during 1988 were infected with HIV.

HIV infection is also a problem among female prisoners in New York. Females are 4 percent of all inmates and have accounted for 4 percent of all inmate cases (41 cases). Thus the cumulative incidence rate from 1981 through 1988 has been equal for male and female inmates (27 cases per 1,000 inmates).[4]

Although the prevalence of HIV infection among female prisoners had never been studied, the statewide newborn HIV seroprevalence data suggested a major HIV problem among women in New York. This study was initiated to assess the extent of and risk factors for HIV infection among women entering the state prison system. Secondary objectives were to determine the association of HIV infection with clinical markers for syphilis, hepatitis B, and tuberculosis and to compare the fertility of seropositive and seronegative women.

Background

The New York State correctional system is the third largest in the United States, with 56 facilities housing 44,637 inmates at the end of 1988 (Mr. Gerald Bala, New York State Department of Correctional Services, personal communication). Of the approximately 1,800 female inmates, 69 percent come from New York City and 8 percent from the four counties closest to New York City. Forty-seven percent of female inmates are Black, 34 percent Hispanic, and 19 percent White. Nearly half (46 percent) have been convicted of drug-related offenses. The median duration of incarceration for women is 24 months (range, 12 to 900 months).

During 1988 a total of 1,017 new female inmates entered the New York State system. All female inmates enter at one central processing facility, where a medical evaluation is completed. The intake process includes a complete medical history, physical examination, and routine laboratory screening tests. Through 1988,

TABLE VI-1—Characteristics of Women Entering New York State Prisons, by Study Inclusion Status, September-December 1988

Characteristics	Included in Study (N=480)	Excluded from Study (N=40)	Difference (95% Confidence Interval)
Mean Age (Years)	29.4 (479)*	29.6 (40)*	+ 0.2 (− 2.6, 2.2)
Mean Education (Years)	10.2 (472)	10.4 (40)	+ 0.2 (− 0.8, 0.4)
Race/Ethnicity			
% Black	44.8 (215/480)	52.5 (21/40)	+ 7.7 (− 8.4, 23.8)
% Hispanic	37.5 (180/480)	32.5 (13/40)	− 5.0 (−20.1, 10.1)
% White	17.7 (85/480)	15.0 (6/40)	− 2.7 (−14.3, 8.9)
% With Residence in New York City	74.6 (344/461)	84.6 (33/39)	+10.0 (− 2.0, 22.0)
% Intravenous Drug Users	28.6 (136/475)	47.6 (10/21)	+19.0 (− 2.8, 40.7)

*For mean age and education, the numbers in parentheses indicate the number of women with available information. Fractions in the parentheses for the other variables indicate the number of women with each characteristic over the total number for whom information was available.

inmates were tested for HIV antibodies only when there was a medical indication, such as clinical evidence of immunodeficiency. In 1989 the testing policy was broadened to encourage all inmates, especially those with known risk factors, to undergo voluntary testing, regardless of their clinical status, so that appropriate counseling and medical therapy could be provided. The system does not segregate inmates on the basis of their HIV serologic status.

Methods

All women entering the New York State correctional system from September through December 1988 were included in this study. During this period no woman entered the system more than once, ensuring that there were no duplicates. Demographic information was abstracted from computerized prison records, and selected information that was routinely collected at prison intake regarding medical history, fertility, intravenous drug use, and other HIV risk factors was abstracted from each woman's prison medical record by trained personnel from the State Departments of Health and Correctional Services. After routine screening for syphilis, hepatitis B, and tuberculosis was performed and the results were abstracted to the data collection forms, information that identified specific inmates was removed from the forms, and a unique random number was used to link each form with the blood samples for HIV serologic testing. This process assured that the HIV test results could not be linked to specific inmates.

Syphilis screening was performed with the rapid plasma reagin test and, for confirmation of reactive specimens, the fluorescent treponemal antibody-absorption (FTA-ABS) test. Hepatitis B surface antigen (HBsAG) was determined by radioimmunoassay. These tests were performed by standard techniques at a commercial laboratory. Tuberculosis screening was performed with the intradermal tuberculin purified protein derivative Mantoux skin test (5 tuberculin units). Induration of 10 mm or greater was considered a positive reaction.

HIV testing was performed by the New York State Wadsworth Center for Laboratories and Research. Specimens were first tested in a single standard HIV-1 enzyme-linked immunosorbent assay (ELISA) (DuPont). Specimens with color development less than test cutoff values were recorded as ELISA-negative and were not tested further. ELISA-positive specimens were examined in a standard Western blot confirmatory assay (DuPont), and seropositivity was determined according to criteria recommended by the Association of State and Territorial Public Health Laboratory Directors and the Centers for Disease Control.[6]

The data from the forms and results of HIV serologic testing were merged and analyzed with computer software from SAS Institute, Inc.,[7] BMDP Statistical Software, Inc.,[8] and the Centers for Disease Control.[9] Chi-square, Fisher exact, and *t* tests were applied to univariate analysis. Standard methodology was used to calculate the 95 percent confidence intervals for differences in proportions[10] and differences in means.[11] Multivariate analysis to assess risk factors for HIV seropositivity utilized logistic regression. For this analysis women who reported having had sex with an intravenous drug user, bisexual male, or persons with AIDS or HIV infection or who had exchanged sex for money or drugs were classified as having practiced high-risk sex. Potential confounding of the estimated mean difference of live births and pregnancies between seropositive and seronegative women was investigated with a one-variable and two-variable stratified analysis.[12]

Results

During the four-month study period, 520 women entered the New York State prison system through its central processing facility. Of these, 480 women comprised the study group, while 25 were excluded because of missing demographic and medical information and 15 because of insufficient blood for HIV testing. Compared with the study group, a greater proportion of the 40 excluded women were Black, residents of New York City, and/or intravenous drug users (Table VI-1).

HIV Status and Risk Behaviors of the Study Group

In the study group 90 (18.8 percent) women were seropositive by ELISA; all were confirmed positive by Western blot. Maximum and minimum seroprevalence rates were estimated for all 520 women. Serologic results were available for 25 of the 40 excluded women: four were confirmed positive, one was positive by ELISA but indeterminant by Western blot, and 20 were negative. Thus the maximum estimated number of seropositive women was 110 (21.2 percent) of the 520 entrants: 90 in the study group plus four seropositives, one indeterminant, and 15 with insufficient blood for testing in the excluded group. If the 15 women with insufficient blood for testing and the woman with indeterminant results are assumed to be seronegative, the minimum estimated number of seropositive women was 94 (18.1 percent).

Of the 90 seropositive women in the study group, 53 were Hispanic, 31 Black, and six White. Eighty were between the ages of 20 and 39 years, and 82 reported New York City as their residence at the time of arrest. Sixty-one (67.8 percent) reported a history of intravenous drug use, and an additional six (6.7 percent) reported sexual contact with persons at risk for HIV infection. The remaining 23 reported no recognized risk behaviors for HIV infection, although six had a positive syphilis serology and another reported exchanging sex for money or drugs (suggesting prior high-risk sexual activity). ditional 11 reported using street drugs nonintravenously, and two others had received tattoos. The remaining three did not report any of these behaviors nor have reactive syphilis serologies.

Associations of Risk Factors with HIV Seropositivity

HIV seroprevalence varied with demographic characteristics (Table VI-2). Women ages 30 to 39 years had the highest rate (25.0). Compared with the rate for Whites, seroprevalence was twice as high among Blacks and four times higher among Hispanics. Seroprevalence increased with decreasing levels of education. Women who resided in New York City at the time of arrest had higher rates than women from the rest of the state. Nearly one-third of women born in Caribbean countries were seropositive.

HIV seropositivity was associated with several potential risk factors for which information was available (Table VI-2). Of the 136 women who reported a history of intravenous drug use, 45 percent were HIV-seropositive, compared with 8 percent of the 339 women who denied intravenous drug use (odds ratio = 9.4). Seroprevalence was also strongly associated with a history of sex with an intravenous drug user, a history of blood transfusion, and evidence of a tattoo on physical examination.

Overall, of women with available test results, 15.3 percent had positive syphilis serology, 2.3 percent were positive for HBsAG, and 13.9 percent had positive tuberculin tests. Of these three clinical markers, a positive syphilis serology was most strongly associated with HIV seropositivity (Table VI-2).

For 472 women, information was available regarding their use or nonuse of specific street drugs (Table VI-3). Among the women denying any drug use, 7.5 percent were seropositive, compared with 8.2 percent of the women who used drugs nonintravenously and 45.9 percent of the women who admitted to intravenous drug use. Among intravenous drug users, those who used cocaine but not heroin had the lowest HIV seroprevalence (25.0 percent), users of heroin and not cocaine had an intermediate seroprevalence (43.6 percent), and users of both cocaine and heroin had the highest seroprevalence (51.3 percent). The corresponding percentages among drug users who denied intravenous use were lower but showed the same increasing trend from "cocaine, no heroin" to "cocaine and heroin."

TABLE VI-3—HIV Seropositivity of Women Entering New York State Prisons by History of Intravenous Drug Use and Type of Drug Used, September-December 1988.*

IV Drug Use Status and Type of Drug Used	Number Tested	Number HIV Positive (%)	Odds Ratio (95% Confidence Interval)

TABLE VI-4—Variables Associated with HIV Seropositivity by Logistic Regression Analysis* for Women Entering New York State Prisons, September-December 1988

Independent Variables	Adjusted Odds Ratio** (95% Confidence Interval)	
Intravenous Drug Use	9.4	(4.8, 18.3)
Race/Ethnicity		
Hispanic	5.8	(1.8, 18.0)
Black	3.3	(1.0, 10.6)
Positive Syphilis Serology	3.2	(1.6, 6.7)
New York City Residence	3.2	(1.1, 9.2)
Blood Transfusion***	2.3	(0.4, 14.5)
Evidence of Tattoo	1.6	(0.8, 3.1)
High Risk Sex†	1.3	(0.7, 2.6)

*The regression model included the seven variables shown, as well as age, as a continuous variable.

**The referent group for Hispanic and Black women was White women, and for women with New York City residence was women with residence in New York State excluding New York City.

***Since the dates of blood transfusions were not available, all women who had ever received a blood transfusion were considered to have this risk factor.

†Women who reported having had sex with an intravenous drug user, bisexual male, person with AIDS or HIV infection, or who exchanged sex for money or drugs were classified as having practiced high risk sex.

TABLE VI-5—Fertility of Women Entering New York State Prisons by HIV Serologic Status, September-December 1988

Measure of Fertility	HIV Positive Women	HIV Negative Women
Mean Number of Pregnancies/Woman* (range)	2.7 (0–8)	2.7 (0–13)
Mean Number of Live Births/Woman (range)	1.8 (0–6)	1.7 (0–8)
Fraction of Women Nulliparous (%)	20/90 (22.2)	113/390 (30.3)

*Two seropositive and 15 seronegative women with incomplete pregnancy histories were excluded from this analysis.

Multivariate analysis identified five factors associated with HIV seropositivity (Table VI-4): women who were intravenous drug users, of Hispanic or Black race/ethnicity, with a positive syphilis serology, or residents of New York City were more likely to be seropositive than women without these factors. There were no interaction effects among any of the variables.

Fertility

Of 21 women who were known to be pregnant, two (9.5 percent) were HIV positive. The mean number of pregnancies, the mean number of live births, and the percentage of women who were nulliparous were similar for HIV-positive and HIV-negative women (Table VI-5). Stratified analysis to control for differences in age, racial composition, and intravenous drug use between seropositive and seronegative women did not change these findings (data not shown).

Discussion

This study, as well as an earlier study of male prison entrants,[5] was crucial in defining the magnitude of the HIV epidemic among New York State prisoners, describing its epidemiology, and promoting increased public health attention to address the epidemic in this high-risk population.

HIV seroprevalence was higher among male (17.4 percent) and female (18.8 percent) entrants to New York State prisons than has been previously reported in any mass screening program or blind epidemiologic study among prisoners in the United States.[1] The seroprevalence among all 520 female entrants during the study period may have actually been closer to our maximum estimate of 21 percent, because many of the excluded women with insufficient blood samples for HIV testing may have had scarred veins from intravenous drug use and been at increased risk for HIV infection. Most seroprevalence rates reported among prisoners in other jurisdictions have been less than 3 percent, with the notable exception of high rates for males (7.0 percent) and females (15.4 percent) entering Maryland State prisons in 1985.[1] The Maryland study found that seroprevalence among male entrants was constant from 1985 to 1987.[13] Follow-up studies of New York State inmates are planned to determine trends in seroprevalence with time.

The blinded design of our study precluded collection of extensive risk information, and the cross-sectional design prevented assessment of temporal associations between HIV infection and risk factors or other infectious diseases. However, the high rate of HIV seropositivity among female inmates is consistent with their relatively high frequency of known risk behaviors, especially intravenous drug use, and the fact that most of them come from New York City, where HIV infection is prevalent. In addition to intravenous drug use, we found that a positive syphilis serology was strongly associated with HIV positivity. Of the 23 HIV-positive women who denied any known risk behavior, six had a positive syphilis test. The association between genital ulcer disease and HIV infection has been previously reported.[14–16] Genital ulcer disease may be a marker for prior high-risk sexual activity and may increase the risk of HIV transmission by disrupting the vaginal or cervical mucosa.

Although HIV infection has not been shown to be associated with tattooing,[17,18] HIV transmission through tattoo needles is biologically plausible, and the possible spread of HIV by this route to prisoners has been reported.[19] In our study, women with tattoos were twice as likely to be HIV-seropositive as women without tattoos (Table VI-2). However, when other possible exposures were controlled in the multivariate analysis, tattoos were not associated with HIV positivity, suggesting that tattooing was not a major factor for transmission in this population.

Our study showed an association between high HIV seroprevalence and Black or Hispanic ethnicity. This association has been described previously among intravenous drug users and attributed to differences in the social setting of drug use and specific drug use behaviors for persons of different ethnic backgrounds.[20–22] Our results may have been affected by these factors, as well as by other unmeasured risk behaviors, such as sexual contact with a person not recognized as being at high risk for HIV infection.

Although other studies have found that intravenous cocaine use is more strongly associated with HIV infection than heroin use,[21,23] our results suggested the opposite (Table VI-3). However, the small number of women in our study limited its power to detect differences by drug use. In any case, caution is needed in interpreting these results, since we had no information on the frequency, quantity, or pattern of intravenous drug use, or on the frequency of high-risk sexual activity.

HIV-positive women in our study reported the same number of pregnancies and live births as the seronegative women, and similar percentages of each group were nulliparous (Table VI-5), even after controlling for differences in age, race, and intravenous drug use between the two groups. These findings suggest that HIV infection did not affect fertility, but because we had no information on the timing of HIV seroconversion relative to the reported pregnancies, the exact relationship between HIV infection and fertility was impossible to assess. Our results are consistent with those of a study among New York City intravenous drug users which found that asymptomatic HIV infection was not associated with a decreased pregnancy rate or an increased risk of adverse pregnancy outcomes.[24] Another study of 136 pregnancies among British women also found no evidence that HIV infection affected the outcome of pregnancy, although there were more spontaneous abortions among the seropositive women.[25]

Determining the impact of HIV infection on fertility would provide important information for interpreting the blind HIV newborn seroprevalence studies that are being conducted widely. These studies provide nearly complete testing of all newborns and therefore are useful measures of HIV-infection among women giving birth and, by extrapolation, among all women.[26] However, if HIV infection substantially reduces fertility, infected women would be less likely to deliver babies, and newborn seroprevalence studies would underestimate infection rates among women. Current evidence suggests that asymptomatic HIV infection may not reduce fertility, but additional studies are needed.

After our study, funding was increased to enable four teams of counselors to provide prisoner education regarding HIV infection and to encourage all prisoners to consider HIV antibody testing. Our study and the earlier study of male inmates[5] also helped to quantify the need for increased medical services for HIV-infected prisoners. Applying the seroprevalence rates from these two studies to the number of entrants at the two prison centers, we estimate that in 1988 approximately 2,200 men and 200 women entered New York State prisons with HIV infection. In addition to routine medical care, these inmates need medical evaluation for newly approved therapies for asymptomatic HIV infection and adequate follow-up of other associated medical conditions, especially tuberculosis, which has shown an alarming increase in association with HIV infection.[27] The problem of perinatal transmission in prison was also apparent from our study, since two of the 21 pregnant women were HIV positive. To address these needs, provision for increased medical care is being planned in New York State prisons; additional seroprevalence studies will be conducted to monitor the HIV epidemic among prisoners in the future.

Summary

Human immunodeficiency virus infection is the leading medical problem among prison inmates in several states. In 1988 a blinded seroprevalence study was conducted on 480 New York female prison entrants to determine the prevalence of and risk factors for HIV infection in this population. Ninety (18.8 percent) women were HIV-seropositive. Seroprevalence was highest among women ages 30–39 (25.0 percent) and varied by ethnicity (Hispanics, 29.4 percent; Blacks, 14.4 percent; Whites, 7.1 percent) and residence (New York City, 23.8 percent; Upstate, 5.1 percent). Nearly half (44.9 percent) of the 136 acknowledged intravenous drug users and one-third (33.8 percent) of the 71 women with a positive syphilis serology were HIV-seropositive. There was no difference in fertility histories between seropositive and seronegative women, and two of 21 pregnant women were seropositive. This study led to increased clinical and prevention services for this high-risk population. ☐

VII. HIV Seroprevalence in Clients of Sentinel Family Planning Clinics

Rachel L. Stricof, MPH
Thomas C. Nattell, MA, MSW
Lloyd F. Novick, MD, MPH

Introduction

Family planning clinics serve predominantly young, sexually active clients, a substantial proportion of whom may be infected—or at risk of infection—with human immunodeficiency virus (HIV). The purposes of this study were to document the prevalence of HIV antibody in women attending sentinel family planning clinics and to monitor the trends in infection over time.

In New York State, there are approximately 200 discrete family planning clinics, located in all counties except Putnam (where negotiations for a clinic are in progress). All but one of these clinics are publicly subsidized. Other groups and/or individuals provide family planning services but d[illegible] have a clinic dedicated solely for t[illegible]pose.

Fam[illegible] planning clinics provide medically approved methods of contraception, medical evaluations, screening and treatment for vaginal infections and sexually transmitted diseases, level-I screening for infertility, and voluntary HIV counseling and testing services.

Most clients in New York State are women. Approximately 75 percent are under age 25. Overall 21 percent are Black and 13 percent Hispanic. [In New York State approximately 14 percent of the population is Black and 12 percent of Hispanic origin (Current Population Survey: March 1988)].

One constraint on this study was that relatively few of the clinics routinely obtain blood specimens. Random sampling of clients and/or clinics was therefore not feasible. Instead the qualifying clinics were considered sentinels, and the results were adjusted for extrapolation to the total population of clients.

Methods

The study was conducted over a period of 26 months, from February 1, 1988 through March 31, 1990.

The study sites were limited to publicly subsidized family planning clinics that routinely drew whole blood specimens for syphilis serology from clients during the initial medical evaluation. Clinics throughout the state were screened for this practice. In early 1988, 38 clinics met this criterion, and 37 agreed to participate. Of the participating facilities, 13 were located in New York City boroughs and the rest in other counties: Westchester, seven; Nassau, four; Onondaga, three; Monroe, five; Orleans, one; Genesee, one; and Erie, three. One clinic in Monroe County was closed shortly after the study was initiated. Five additional clinics (Rockland, two; Orange, two; Nassau, one) entered the study after changes in their routine blood-collection practices.

Study subjects were limited to clients undergoing an initial medical evaluation for contraceptive services. Clients seen for annual or follow-up visits were excluded to avoid repeat testing of the same individuals over time. Individuals seen solely for pregnancy testing were also excluded, because blood specimens were not routinely obtained on this population. Clients seen only for HIV counseling and testing were excluded to minimize self-selection bias.

If a client met these criteria, a seroprevalence study test requisition (SSTR) form was completed by the clinic staff and submitted along with the routine laboratory request form and blood specimen to a contract laboratory. The completed form contained the client's age, race or ethnicity, and county and zip code of residence, as well as the clinic site and the month and year of specimen collection. Identifying information (e.g., name, street address, or medical record number) was not collected; thus the information could not be traced back to the individual client.

If serum was left over after all routine laboratory tests were performed, the contract laboratory would pipette at least 0.5 ml into a tube labeled with the blind seroprevalence number and send the serum with the SSTR form to the New York State Department of Health's Wadsworth Center for Laboratories and Research. No additional blood was drawn for this study.

When the blood drawn was insufficient for blind HIV testing, the SSTR alone was sent to the Department of Health. These data were used to estimate any bias from the loss of specimens. The data were not used for any other analysis.

The Wadsworth Center performed an ELISA (enzyme-linked immunosorbent assay) (DuPont) for HIV antibody. ELISA reactives were confirmed with a Western blot (in-house assay until May 1988, then DuPont). All Western blots were interpreted by the latest Association of State and Territorial Public Health Laboratory Directors criterion[1] for reactive specimens, i.e. virus-specific bands in at least two of the following major band locations: gp160/120, gp41, or p24. Specimens with other major virus-specific bands were interpreted as equivocal. All other specimens were considered nonreactive.

Seroprevalence rates were calculated as: (number of Western blot reactives)/(total number of specimens minus equivocals). Because the specimens could not be traced to individual clients, we could not request second samples for reevaluation of equivocals.

Age-specific seroprevalence rates were calculated in five-year intervals for ages 15 to 39. Individuals under age 15 were grouped, as were those over age 39. Racial/ethnic-specific seroprevalence rates were calculated for non-Hispanic Whites, non-Hispanic Blacks, Hispanics, Others, and Unknowns. Others and Unknowns had to be combined due to small cell sizes for some combinations of age and race/ethnicity groups.

HIV seroprevalence rates by quarter-year of clinic visit were calculated to describe changes in seroprevalence over time. For this analysis three of the 37 initial clinics were eliminated: one that closed early in the study and two that closed later. Trends were calculated only for the 34 clinics that participated throughout the entire study period.

To estimate the completeness of the data set, we used the number of initial medical examinations in 1988 reported by each participating clinic to the New York State Department of Health's Bureau of Reproductive Health. This number was compared to the number of specimens submitted during the first year of the study (February 1988–January 1989). Clinic records were available from all but one site in upstate New York.

Bureau of Reproductive Health statistics were also used to adjust for differences between the sentinel clinic clients and the overall family planning clinic population. The age, racial/ethnic, and residence distributions of the two groups were compared and the HIV seroprevalence rates were adjusted directly for differences, using the overall population as the standard.

The results of the sentinel clinic study were compared to the results of the Newborn HIV Seroprevalence Study. Sentinel clinic rates were adjusted for the differences in age, racial/ethnic, and residence distributions. The adjusted rates were calculated for New York City, New York State exclusive of New York City, and statewide, using the distribution of childbearing women as the standard population.

Between February and July 1988 a separate, unlinked HIV risk assessment questionnaire was administered to clients of 30 family planning clinics by clinic staff. Participation in the risk study was voluntary and not limited to the subset of women seen for an initial medical evaluation. The results were submitted to the New York State Department of Health without patient identifiers. Participation was voluntary on the part of the facility and the clients.

The questionnaire included items on the client's age; race/ethnicity; county of residence; history of intravenous drug use; history of living in a high-risk country (as defined by the Centers for Disease Control); history of being a sex partner of a bisexual male, drug user, hemophiliac, or person with AIDS or HIV infection; and maximum number of sex partners in any six-month period since 1978 (0, 1, 2, 3, or 4+).

Results

Sentinel Clinic Results

Between February 1, 1988 and March 31, 1990, a total of 28,745 specimens were obtained from women having initial medical examinations in the sentinel family planning clinics. Of these specimens, 896 (3 percent) had an insufficient quantity of serum left over for analysis. An additional 1 percent were not tested due to improper shipping, leakage of tubes, or blank forms or because the specimen was obtained from a male client. Twelve (0.04 percent) had equivocal HIV test results and were eliminated from the analysis. Of the 27,549 remaining specimens 144 (0.52 percent) were HIV antibody-positive.

Fourteen of the 41 clinic sites (one in New York City, 13 in New York State exclusive of New York City), which contributed 11.8 percent of the study population, had no seropositives identified during the study period. Eight clinics (two in New York City) had rates of seropositivity between 0.01 and 0.50 percent; 11 clinics (six in New York City) had rates between 0.51 and 1.00 percent; and eight clinics (four in New York City) had rates in excess of 1 percent. The highest seroprevalence rate was 3.91 percent, detected in a mobile clinic in New York City.

The highest seroprevalence rate by residence of the client was detected among residents of New York City, with 0.82 percent identified as positive. The rates by boroughs (and the numbers tested/received) were: Manhattan, 0.73 percent (15/2,050); Bronx, 0.98 percent (20/2,031); Kings, 0.81 percent (50/6,187); Queens, 0.84 percent (20/2,387); and Staten Island, 0.67 percent (6/891).

Residents living elsewhere in the state had a 0.24 percent rate of seropositivity. Clients from counties nearest New York City (Westchester, Nassau, and Rockland) had five times the seroprevalence of residents from other counties (Erie, Monroe, Orleans, Genesee, Onondaga, and Orange): 0.54 versus 0.11 percent, respectively.

No seropositives were detected among the 805 individuals tested under the age of 15, and three seropositives (0.42 percent) were detected among the 722 individuals age 40 or more (Table VII-1). Between these groups HIV seroprevalence increased with age. Women 35–39 years old had approximately nine times the HIV seroprevalence rate of 15–19 year olds (1.56 versus 0.18 percent). The trend of increasing HIV seroprevalence with age was seen for all racial/ethnic groups.

Minority women (non-Hispanic Black or Hispanic) had an HIV seroprevalence of 0.76 percent (Table VII-1). This was about six times the rate detected among non-Hispanic Whites (0.13 percent).

HIV seroprevalence rates by quarter-year of clinic visit are shown in Table VII-2. The highest rates (0.63 and 0.71

*Data limited to 34 clinics that participated during the entire study period.

percent) occurred in the second quarter of 1988 and first quarter of 1990. The lowest rate (0.34 percent) was detected in the incomplete first quarter of 1988. No trend over time is evident.

Extrapolation to All Family Planning Clinics

According to Bureau of Reproductive Health statistics, a statewide total of 68,644 initial medical examinations at family planning clinics were done in 1988. Of these examinations, 15,112 (22 percent) involved clients at the sentinel clinics. During the first year of the study (beginning in February 1988) 12,575 client specimens were included in the analysis. This is an estimated sampling rate of 83 percent in the sentinel clinics for 1988: 86 percent in New York City, 80 percent in New York State exclusive of New York City.

Sentinel clinic clients were more likely to be non-Hispanic Black (36.5 percent) or Hispanic (25.3 percent) than were clients in general (21.2 percent and 13.5 percent, respectively). The age distributions were similar: women under age 25 were 72.3 percent of clients at sentinel clinics and 73.4 percent at all clinics statewide.

After adjustments for differences in the racial/ethnic and residence distributions, the extrapolated HIV seroprevalence rates for all family planning clinic clients were: New York City, 0.82 percent; New York State exclusive of New York City, 0.15 percent; and statewide, 0.31 percent.

TABLE VII-3—Risk Factors for HIV Infection of Clients at Sentinel Family Planning Clinics, February 1988–July 1988

*SP—Sexual partner(s).
**SP—Sexual partners in a six-month period since 1978.

Comparison to Newborn Seroprevalence Data

Because there were substantial differences between the demographic profiles of family planning clinic clients and those of childbearing women, adjusted seroprevalence rates were calculated using the age, racial/ethnic, and residence distributions of childbearing women as the standard.

The adjusted seroprevalence rates were: New York City, 1.53 percent; New York State exclusive of New York City, 0.25 percent; and statewide, 0.92 percent. These figures were 24 to 47 percent higher than the rates for childbearing women in the Newborn HIV Seroprevalence Study: New York City, 1.24 percent; New York State exclusive of New York City, 0.17 percent; and statewide, 0.66 percent.[2]

Risk Factors

Thirty sentinel clinics participated in the voluntary risk assessment study. Risk assessment forms were completed on 6,892 clients, who were generally of the same age (71 percent under age 25) as the whole study population. The risk-assessment group was more likely to reside in New York City and to be non-Hispanic Black (50 percent) or Hispanic (27 percent) than the overall sentinel population. (Of the risk-assessment group 21 percent were non-Hispanic White, and 3 percent were of Other or Unknown race/ethnicity.)

The number and percent of clients in the sentinel clinics admitting to the selected risk factors for HIV infection are presented in Table VII-3. The most frequently reported risk factors were having sex with four or more sex partners in a six-month period, having lived in a high-risk country, having had sex with an intravenous drug user, and having had sex with a bisexual male. Of all the participating clients, 583 (8.46 percent) admitted to at least one of the risk factors. Fifty-nine (11.64 percent) of the pregnant women admitted to at least one risk factor.

The women who volunteered for this study were not limited to those in the seroprevalence study. Not all sentinel clinics participated, and the extent of participation varied considerably among the participating clinics. For these reasons the results should be considered background information and not interpreted to explain seroprevalence results obtained for the full study population.

Discussion

Family planning clinics serve predominantly young, sexually active clients. In this study of 41 sentinel clinics, approximately one in 200 clients was infected with HIV.

The clinics in this study were not representative of all of the approximately 200 clinics in the state. Sentinel clinics were limited to those that routinely drew blood for syphilis serology on all initial clients. These clinics tended to be in areas with higher syphilis incidence rates and thus potentially higher HIV infection rates. The crude and adjusted HIV seroprevalence rates obtained in this study may overestimate the actual rate for the total family planning clinic population. The true rates are likely to be closer to those found in the Newborn HIV Seroprevalence Study.

A slightly low bias in statewide rates may have been introduced by the 896 specimens that were insufficient for testing. These specimens represented clients who resided primarily in New York City (79.7 percent). The 896 clients resembled the entire study group in their age distribution (71.5 percent under age 25) and resembled other New York City clients in their racial/ethnic distribution (non-Hispanic White, 21.0 percent; non-Hispanic Black, 42.5 percent; Hispanic, 34.4 percent; Other, 2.1 percent).

After reviewing the results of this and other seroprevalence studies involving New York State residents, the New York State Department of Health required HIV education, counseling, and testing programs as a condition of funding in all publicly subsidized clinics for family planning and prenatal care.

Since virtually all women seen in these clinics are sexually active, they are potentially at risk for HIV infection. Knowledge of an individual's HIV infection status is important to prevent transmission, particularly vertical transmission from mother to infant, and to prevent or defer certain complications of HIV infection with early therapeutic intervention.

In addition to providing HIV counseling and testing, family planning and prenatal care clinics must be prepared to provide or offer referral for care for their HIV-positive clients.

Summary

In February 1988 the New York State Department of Health initiated a study to determine the prevalence of HIV antibody in women attending selected, publicly subsidized family planning clinics. During a 26-month study period, 27,549 blood specimens were obtained from women having an initial medical examination in 41 clinic sites throughout the state. Of these clients 144 (0.52 percent) were seropositive.

The HIV seroprevalence rate increased with age to a high of 1.56 percent for 831 women ages 35 to 39. The seroprevalence rate for non-Hispanic Black or Hispanic clients (0.76 percent) was about six times the rate for non-Hispanic Whites (0.13 percent). No overall increasing or decreasing trend in prevalence of HIV infection was detected during the study period. ☐

VIII. Hospitalization of HIV-Seropositive Newborns with AIDS-Related Disease within the First Year of Life

Donna M. Glebatis, MS
Lloyd F. Novick, MD, MPH
Andrew Stacy, BA

Introduction

HIV seropositivity in a newborn is a reflection of the mother's HIV infection status, not necessarily that of the infant.[1,2] Only a minority of seropositive infants are actually infected, remaining HIV-positive after 18 months. Studies of perinatally acquired infection have shown wide variation in the rates of maternal transmission.[3-10] Factors such as low numbers of study subjects, loss to follow-up, neonatal deaths from indeterminate causes, absence of detectable antibodies in some infants with HIV-related illness,[10-12] and asymptomatic HIV-positive infants[9] erode investigators' ability to determine the true rate of vertical transmission of HIV infection.

This study was initiated in an attempt to measure the impact of HIV-seropositive newborns on the hospital care system. Our strategy was to determine the proportion of HIV-seropositive newborns who are hospitalized for an AIDS-related diagnosis (ARD) during their first year of life and to characterize those hospitalizations. This information can be used to plan the inpatient services required for HIV-infected infants.

Methods

The Statewide Planning and Research Cooperative System (SPARCS), maintained by the New York State Department of Health, collects diagnostic, demographic, and financial data on every hospital discharge in New York State.[13] Data on each hospital discharge include patient demographic information and primary and secondary diagnostic and procedure codes.

All hospital discharges from December 1987 through June 1989 were extracted from the SPARCS data base for any infant with a date of birth from December 1987 through June 1988 and an ARD of ICD-9CM 042, 043, 044, 795.8, or other selected codes (see Appendix) in any of the five diagnostic code categories. If a hospitalization had more than two ARDs, the code with the highest designation in the hierarchy listed above was used in the analysis.

Since SPARCS records represent hospital discharges and not individuals, multiple hospital discharges of an individual were collapsed into a single longitudinal case by linkages based on the date of birth, gender, and county of residence. Additional data elements such as dates of admission and discharge, medical record number, zip code of residence, race/ethnicity, patient disposition, and transfer status were examined to validate the case formation.

The number of HIV-seropositive infants who were born in each month from December 1987 to June 1988 was determined from the Newborn HIV Seroprevalence Study.[14]

The newborn seroprevalence and SPARCS data bases do not contain personal identifiers and cannot be linked. The analysis was therefore restricted to comparing, for each month of birth, the number of HIV-seropositive newborns and the number of infants hospitalized with an ARD within the first year of life. Frequencies were tabulated on the number of hospitalizations, the length of stay, each AIDS-related ICD-9-CM diagnostic code, age at first hospitalization, and case fatality rates.

Results

A total of 995 HIV-seropositive newborns born December 1987 through June 1988 were confirmed in the Newborn

Two +	8	41	20
Total	31	151	21

bers of the hospitalized set were members of the seroprevalence set, 15 percent of HIV-seropositive infants born in these seven months were hospitalized with an ARD within 12 months of birth. The monthly ratios ranged from 14 to 18 percent (Table VIII-1).

The 151 ARD cases had a total of 240 hospitalizations during the 12 months of follow-up. Most (73 percent) had only one hospitalization, 16 percent had two, 5 percent had three, and 6 percent had four to eight. Cases with a diagnostic code of 795.8 had the greatest proportion of multiple admissions (Table VIII-2).

The multiple admission patterns are influenced by a high case fatality rate of 21 percent (Table VIII-3). Of the 31 deaths, 23 (74 percent) occurred during the first hospitalization. As would be expected, cases with a 042 (AIDS) diagnostic code had the highest fatality rate (40 percent), compared with 18 percent for those with a 043 or a 044 code and 9 percent for those with a 795.8 or other code.

The 240 hospitalizations of the 151 cases comprised a total of 5,772 patients days, ranging from one to 368 days per hospitalization. Nearly half of the hospitalizations had a length of stay (LOS) exceeding 10 days (Figure 1). Cases with 042 codes had the greatest median LOS, 15 days (Table VIII-4). The other four categories had similar median LOS, ranging from 7.5 to 9.0 days.

Twenty-eight percent of the cases were first hospitalized for an ARD during the birth stay or within 90 days of birth (Figure 2). More than half (56 percent) were first hospitalized within six months of birth. Fifteen cases had an ARD at the hospitalization of birth. Seven of these 15 had a diagnostic code of 795.8; all 15 had an accompanying illness, such as severe infection or drug withdrawal. The average LOS for an ARD at the hospitalization of birth was 68.6 days.

Discussion

In this study, 151 of 995 (15 percent) newborns positive for HIV antibody were hospitalized with an ARD during the first year of life. Assuming maternal transmission rates of 25 to 50 percent,[3–10,15,16] it is estimated that of the 995 HIV-positive newborns, 250–498 infants were actually HIV-infected. Thus approximately 30–60 percent of the HIV-infected infants were hospitalized with an ARD within the first year of life.

The accuracy of this estimate is difficult to assess due to problems inherent in ecologic comparisons, including migration, deaths occurring outside the hospital, underreporting or inaccurate reporting of ARD cases to SPARCS, and missing and unknown data in both data bases. To minimize the impact of migration, we only included New York State residents from both files. However, 6 percent of the ARD cases included in this study had a county of residence at first hospitalization that was not a county of residence at birth for HIV-seropositive infants born in the same month.

Undercounting of ARD cases could occur when an infant had HIV-related illness, such as a bacterial infection, but was not coded as having HIV infection. This type of underreporting was assessed among 199 adult AIDS cases identified through a one-day hospital bed census and verified through chart review. SPARCS records were identified for 188 of those cases, and 177 indicated one of the current or discontinued HIV codes (personal communication, unpublished report, Benedict I. Truman, MD, Gerald Kaufman, PhD). To assess the accuracy of pediatric AIDS reporting to SPARCS, the AIDS Surveillance Program conducted chart reviews on 56 infants reported to SPARCS with a 042 diagnostic code in 1986. Half the cases were CDC-defined AIDS, 40 percent were AIDS-related conditions or suspect AIDS, and 10 percent were either adult or duplicate cases (personal communication, unpublished report, Benedict I. Truman, MD, Gerald Kaufman, PhD).

These analyses suggest that SPARCS data capture approximately 90 percent of HIV-related hospitalizations but are not very accurate in distinguishing AIDS from

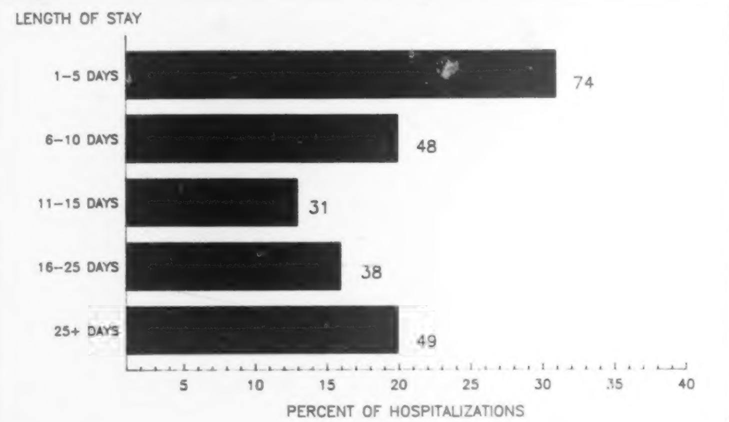

FIGURE 1—Distribution of Hospitalizations of ARD Cases by Length of Stay (in Days)

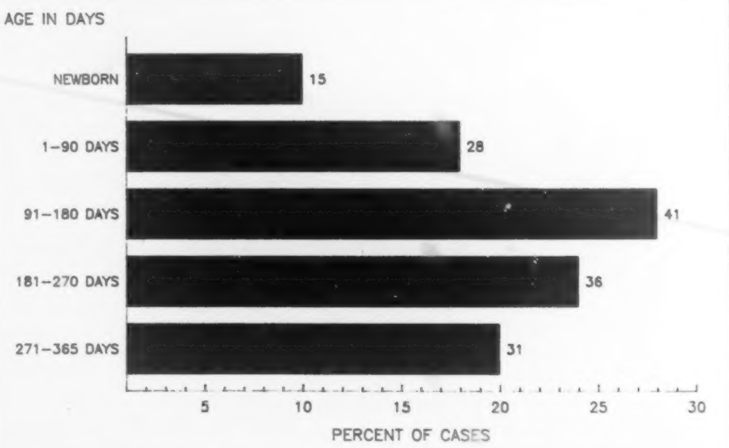

FIGURE 2—Distribution of ARD Cases by Age in Days at First Hospitalization

ARD. The latter finding was also substantiated in this study, in which nine cases switched from a 042 diagnosis to a 043, 044, or 795.8 diagnosis in subsequent hospitalizations.

Our finding that 15 percent of seropositive newborns are hospitalized with an ARD within 12 months of birth is consistent with two recent reports on pediatric AIDS.[9,10] The first study, conducted in Zaire, included HIV-seropositive infants who had lived beyond one month of age. Of the 412 infants studied, 13.4 percent had developed AIDS within 12 months of life, according to a definition based on the WHO (World Health Organization) clinical case definition of pediatric AIDS in Africa.[10] In the second study, from France, 19 (11 percent) of 177 seropositive infants developed severe forms of HIV infection within 18 months, based on the CDC classification for children.[9]

These two studies are not directly comparable with ours, because they used different study populations and case definitions. The French and Zaire studies were facility-based, whereas ours used the population-based Newborn HIV Seroprevalence Study and hospital discharge data. In addition, due to confidentiality concerns, our study could not identify HIV-seropositive or ARD cases but relied on an ecologic comparison based on month of birth. However, the similarity of results in the three studies, along with the internal consistency of month-to-month ARD/HIV ratios in this study, lend support to the accuracy of these estimates.

The results of this study are based on seven months (December 1987 through June 1988) of newborn seroprevalence data. This procedure will be conducted on an ongoing basis to project future hospital care needs of HIV-infected infants and to provide more information regarding maternal transmission and latency of HIV-related diseases in this population.

Summary

The purpose of this study was to estimate the proportion of HIV-seropositive newborns hospitalized for an AIDS-related diagnosis within 12 months of birth and to characterize these hospitalizations. The number of HIV-seropositive infants born December 1987 through June 1988 was derived from the blinded New York State Newborn HIV Seroprevalence Study. The number of infants who were born in these same months and hospitalized with an ARD within 12 months of birth was obtained from a data base containing information on all hospital discharges in New York State. Comparisons were made on the basis of month of birth.

Of infants born during the study period, 995 tested positive for HIV antibody, and 151 infants (15 percent) were hospitalized with an ARD within 12 months of birth. The 151 ARD cases had a total of 240 hospitalizations, accounting for 5,772 patient days. Fifty-six percent of the ARD cases were diagnosed within six months of birth. ☐

IX. HIV Seroprevalence in a Facility for Runaway and Homeless Adolescents

Rachel L. Stricof, MPH
James T. Kennedy, MD
Thomas C. Nattell, MA, MSW
Isaac B. Weisfuse, MD
Lloyd F. Novick, MD, MPH

Introduction

Despite the clinical and epidemiologic importance of HIV infection among adolescents, our knowledge of the extent of infection in this population in New York State has been limited, relying on AIDS case reports and data on military recruits. As of December 31, 1989, a total of 67 cases of AIDS in individuals 13–19 years old had been reported statewide, 45 males and 22 females. Their risk factors were reported as follows: 21 were homosexual/bisexual males, 12 were intravenous drug users, three were homosexual intravenous drug users, 10 were heterosexual contacts of persons at risk, 14 received blood products, three were foreign-born, and risk factors were not determined for four.

Military recruit data for New York State residents from October 1985 through December 1988 revealed a seroprevalence of 0.06 percent for persons 17–19 years old (communication from Centers for Disease Control; Quarterly Data Report on HIV in Civilian Applicants for Military Service, June 22, 1989). Thirty males and eight females were identified as seropositive for HIV.

Due to this limited availability of information on adolescents, a seroprevalence study was initiated in Covenant House New York, a facility serving runaway and homeless youth in New York City. Although this population is not representative of adolescents in general, it was selected as a sentinel group of high-risk youth. The study was designed to determine HIV seroprevalence among adolescents receiving health care at the facility, to ascertain selected demographic characteristics (age, race/ethnicity, gender), to assess trends in seroprevalence over time, and to determine the risk factors associated with HIV infection in this population.

Background

Covenant House New York predominantly serves adolescents under the age of 21. It consists of a crisis center, which can accommodate more than 300 individuals a night; a drug treatment program for 26 residents, with a 30-day average stay; a mother-child shelter; an outreach program (vans that go out at night); and a long-term transitional living program.

A recent survey[1] of 168 Covenant House adolescents revealed the following sociologic characteristics:

- The average length of time away from home was 90 weeks.
- Alcohol was used by 80 percent, marijuana by 68 percent, cocaine by 48 percent, and crack by 38 percent.
- Intravenous drug use was low (6 percent).
- Nearly all (91 percent) were sexually active, with an average of 2.8 sexual partners weekly (range, one to 20).
- Twenty-nine percent admitted to having exchanged sex for food, money, shelter, or drugs.
- Most (62 percent) reported having been arrested.
- Almost half (46 percent) reported having been treated as outpatients for psychiatric problems, and 18 percent had received inpatient psychiatric treatment.

Approximately 50–60 percent of the adolescents seeking shelter in Covenant House New York are seen in the health services department. Individuals are referred for health services immediately if they are on medication, placed in one of the group homes, a mother-infant pair, or deemed to have a health problem on intake. All others are referred if they remain in the facility for 24–48 hours. At the first visit a complete health assessment is performed, which includes a physical examination, urinalysis, complete blood count, and serologic test for syphilis.

TABLE IX-1—HIV Seroprevalence by Quarter among Runaway and Homeless Adolescents, October 1987–December 1989

Quarter	Number Positive	Number Tested	Percent Positive
4th 1987	22	280	7.9
1st 1988	14	315	4.4
2nd 1988	18	254	7.1
3rd 1988	20	292	6.9
4th 1988	11	250	4.4
1st 1989	16	300	5.3
2nd 1989	13	245	5.3
3rd 1989	20	415	4.8
4th 1989	8	316	2.5
Total	142	2,667	5.3

Methods

Study subjects were limited to Covenant House New York clients undergoing an initial medical evaluation between October 1, 1987 and December 31, 1989. Clients seen for annual or follow-up visits were excluded to avoid repeat testing of the same individuals over time. The study was limited to persons 15–20 years old, because few individuals under the age 15 or over age 20 visit the clinic and we wanted to be able to assure anonymity.

If a client met the inclusion criteria, an HIV seroprevalence study test requisition (SSTR) form was completed by the clinic staff. The completed form contained the adolescent's age, race or ethnicity, gender, and most recent county and zip code of residence, as well as the month and year of specimen collection. No personal identifier (e.g. name, previous street address, or medical record number) was recorded.

The SSTR form was held with the specimen until all routine laboratory tests were completed. If serum was left over, the laboratorian would pipette at least 0.5 ml into a tube labeled with the blind seroprevalence number and send the serum with the SSTR form to the New York State Department of Health's Wadsworth Center for Laboratories and Research for HIV testing.[2] No additional blood was drawn for this study. If there was not a sufficient quantity of blood left over, the demographic data alone were sent to the Department and entered into the data base.

In May 1988 a risk-assessment component was added to the study design. Information routinely obtained by the clinic staff and documented in the medical record was abstracted onto a separate risk assessment form with the blind seroprevalence number. This information included, where applicable, the gender of sex partners; the history of intravenous drug use (heroin or cocaine), crack use, prostitution, blood transfusion, and/or sexually transmitted disease; and the sex partners' history of drug use, homosexual/bisexual activity, or HIV status.

The information recorded on the SSTR form, including the HIV test result, was merged with the risk-assessment information and analyzed using computer software from SAS Institute, Inc; BMDP Statistical Software, Inc; the Centers for Disease Control[3]; and Epistat Services.[4]

Overall HIV seroprevalence rates were calculated by quarter-year of clinic visit. Chi-square tests for trend were applied to the data.[4]

Seroprevalence rates were calculated by gender, year of age, and for three racial/ethnic categories: non-Hispanic Whites, non-Hispanic Blacks, and Hispanics. The effects of the various demographic characteristics were assessed by multiple regression analysis after controlling for potential confounding effects of the others.

Univariate analysis for risk factors associated with HIV infection was performed with odds ratios and confidence intervals.[5] Mutually exclusive categories were established in the following hierarchical order: intravenous-drug-using homosexual/bisexual males, homosexual/bisexual males, intravenous drug users, blood transfusion recipients, persons with sex partners known or at risk for infection, persons with a history of sexually transmitted disease, prostitutes, and crack users. Individuals reporting none of these risk factors formed the reference group.

Demographic characteristics and/or risk factors independently associated with HIV infection were determined by multiple logistic regression after controlling for the effects of the others. Age, race/ethnicity, and risk factors derived from the univariate analysis were forced into the model. Adjusted odds ratios and confidence intervals were derived from the parameter estimates and standard errors.

Results

Over the 27-month study period, 2,667 specimens were analyzed for HIV antibody, and 142 (5.3 percent) were found to be positive. Five specimens were not tested due to insufficient serum, and eight equivocals were eliminated from the analysis.

The HIV seroprevalence rates by quarter are presented in Table IX-1. There was a tendency toward a decrease in seroprevalence over time, but the decline was not sufficient overall ($p = 0.27$) or for any subset of the population (males, females, non-Hispanic Whites, non-Hispanic Blacks, Hispanics, 15–16-year-olds, 17–18-year-olds, or 19–20-year-olds). A tendency toward a decline approaching statistical significance was found for females ($p = 0.06$), Blacks ($p = 0.08$), and 19–20-year-olds ($p = 0.09$).

Seroprevalence rates by age, race/ethnicity, and gender are presented in Table IX-2. The rates increased from 1.3 percent for 15-year-olds (not shown) to 8.6 percent for 20-year-olds. Hispanics had the highest seroprevalence rate, followed by non-Hispanic Whites and non-Hispanic Blacks. For males the rate was 6.0 percent; for females, 4.2 percent. However, after controlling for each of the other demographic characteristics, age was the only variable found to be associated with HIV seropositivity.

Between May 1988 and December 1989 risk-assessment forms were submitted on 1,758 individuals, 1,039 males and 719 females. The unadjusted HIV seroprevalence rates and univariate risk-factor analyses are presented in Table IX-3. HIV infection in males was associated with intravenous drug use, homosexual/bisexual activity, history of a sexually transmitted disease, prostitution, and crack use. HIV infection in females was associated with history of another sexually transmitted disease.

The results of the multivariate risk-assessment analyses are summarized in Table IX-4. After controlling for the confounding effects of the other variables listed, HIV infection in male adolescents was found to be associated with the following independent risk factors in declining order: homosexual/bisexual activity, prostitution, having had another sexually

TABLE IX-2—HIV Seroprevalence Rates by Demographic Characteristics among Runaway and Homeless Adolescents, October 1987–December 1989

Demographic Characteristics	Number Positive*	Number Tested*	Percent Positive	Odds Ratio**	95% Confidence Interval**

Prostitution	2	16	12.5	8.5	0.8, 47.9
Crack Use	2	69	2.9	1.8	0.2, 9.1
No Risk Indicated	8	483	1.7	1.0	

Abbreviations: IVDU, intravenous drug use; STD, sexually transmitted disease (other than HIV infection).

transmitted disease, and crack use. For females no risk factors were independently associated with HIV infection, although there was a tendency toward an association for prostitution and having had another sexually transmitted disease.

Discussion

This seroprevalence study of a sentinel group of runaway and homeless adolescents disclosed an alarming rate of HIV infection. More than 5 percent were seropositive. Although not representative of adolescents in general, they demonstrate the magnitude of the problem for a large and definable group at one end of the spectrum. These findings have implications, not only for clients of this facility, but also for other groups who interact with runaways and homeless and are consequently at risk.

These homeless youths come from the streets of New York City; their environment is characterized by drug use, prostitution, poverty, and crime. The seroprevalence data indicate an association between HIV infection and prostitution, history of other sexually transmitted diseases, and crack use, in addition to other, previously defined risk factors. Exchanging sex for food, money, shelter, or drugs with multiple sexual partners, some of whom are infected, is the most likely explanation for HIV transmission in this group of adolescents.

Since we were limited to obtaining risk information that was documented in the medical record during the standard course of medical practice, the data probably do not reflect the full incidence of these risk behaviors and should be interpreted with caution. Data provided by Margetson and Lipman[1] suggest that prostitution and crack use were underreported in our study.

The adolescents in this study are highly susceptible hosts living in a hazardous environment. They are regularly exposed to infectious agents, including HIV. Host factors include high levels of sexual activity, unprotected sexual intercourse, and homosexual/bisexual activity in males. Environmental factors include poverty and the necessity to support oneself and obtain drugs in an environment where drugs, prostitution, sex, and infection are commonplace and linked. Prevention activities face the challenge of inducing change, not only in the individuals, but in the external factors that facilitate exposure.

Prevention initiatives must start earlier than the adolescent period if a satisfactory impact is to be attained. All schools in New York State must provide basic HIV education. Regional training coordinators from the New York State Education Department are helping to develop and implement these programs.

The New York State Department of Health, using state and federal funds, has contracted with a variety of community-based organizations to provide HIV education, counseling, and testing services as well as special living arrangements or referrals, basic needs (food, clothing, shelter, etc.), psychosocial support, and medical services to high-risk adolescents.

Summary

In October 1987, the New York State Department of Health initiated a study to determine the prevalence of antibody to HIV in clients of a facility for runaway and homeless adolescents in New York City. A risk-assessment component was added in May 1988. As of December 1989, a total of

TABLE IX-4—Multivariate Analysis of Factors Associated with HIV Infection among Runaway and Homeless Adolescents, May 1988–December 1989

Demographic Characteristic or Risk Factor	Odds Ratio (95% Confidence Interval)*	
	Males	Females
Race/Ethnicity		
Non-Hispanic White	1.0	1.0
Non-Hispanic Black	1.0 (0.4, 2.6)	1.1 (0.3, 3.8)
Hispanic	2.0 (0.8, 5.2)	0.6 (0.1, 3.3)

History of STD**	2.4 (1.1, 5.0)	2.3 (0.9, 6.2)
Prostitution	2.8 (1.0, 7.5)	4.0 (0.9, 18.3)

*After controlling for age.
**Sexually transmitted disease (other than HIV infection).

2,667 adolescents had been tested, and 142 (5.3 percent) were found to be HIV-seropositive (males 6.0 percent, females 4.2 percent). The seroprevalence rate increased from 1.3 percent for 15-year-olds to 8.6 percent for 20-year-olds. Hispanics had the highest seroprevalence rate (6.8 percent), followed by non-Hispanic Whites (6.0 percent) and non-Hispanic Blacks (4.6 percent). HIV seropositivity was associated with intravenous drug use, male homosexual/bisexual activity, prostitution, and history of another sexually transmitted disease. The alarmingly high prevalence of HIV infection in this selected population illustrates the immediate need for prevention programs for adolescents. □

X. The AIDS Epidemic in New York State

Perry F. Smith, MD
Jaromir Mikl, MSPH
Sue Hyde, BS
Dale L. Morse, MD, MS

Introduction

Surveillance for cases of acquired immunodeficiency syndrome (AIDS) has provided important information for characterizing and controlling the epidemic. Even before the human immunodeficiency virus (HIV) had been identified in 1983 and 1984,[1,2] AIDS surveillance demonstrated that gay men and intravenous drug users (IVDUs) bore a disproportionate share of the burden of disease.[3] Surveillance data provided the first information about the modes of transmission of HIV and were thus the basis for early recommendations to limit its spread.[4]

New York State reported some of the first AIDS cases and has the highest number of cases in the nation, mostly from New York City. This report describes the AIDS epidemic statewide and compares it with the epidemic in the rest of the nation. It also compares data from the state's Newborn HIV Seroprevalence Study with AIDS surveillance data for women.

Methods

Both the New York State Department of Health (DOH) and New York City DOH maintain active surveillance for AIDS cases, including regular solicitation of reports from hospitals. New York City DOH staff investigate all cases reported within the city; New York State DOH staff investigate cases in New York State exclusive of New York City. Once a suspect case is identified, trained surveillance staff review the patient's medical records to collect demographic, risk-factor, and clinical information. Vital status is regularly updated by systematic review of death certificate reports and by encouraging hospitals to report deaths to surveillance staff.

Throughout the epidemic, all suspect cases have been evaluated according to the national surveillance case definition, which has been expanded twice, in 1985 and 1987.[3,5,6] Each case was evaluated by the criteria current when the case was investigated. Cases meeting more than one definition were classified hierarchically according to the earliest definition that they met.

Special case ascertainment studies indicate that 75-85 percent of diagnosed AIDS cases in New York City are eventually reported,[7] as are more than 95 percent of patients discharged with AIDS-related diagnoses in New York State exclusive of New York City.[8]

Both the State and New York City DOH report their confirmed cases independently, without identifying information, to the Centers for Disease Control (CDC) for national surveillance. The New York State DOH also maintains a statewide computerized AIDS registry in which the state and city case files are merged.

For comparison with the statewide case data, the number of cases in the rest of the United States was determined from summary national AIDS surveillance data reported to CDC through November 1989.[9] For each subgroup comparison the number of cases reported statewide was subtracted from the corresponding national total. To ensure comparability between the statewide and national data, we selected all cases registered in New York State exclusive of New York City as of October 31, 1989, and all cases registered in New York City as of November 17, 1989—the final dates of data transfer for the national surveillance report.

Geographic classification of persons with AIDS was based on their residence at the time they met the national surveillance case definition, except for cases outside New York City before July 1989, where we used the residence at onset of symptoms. Cases were also classified as adults/

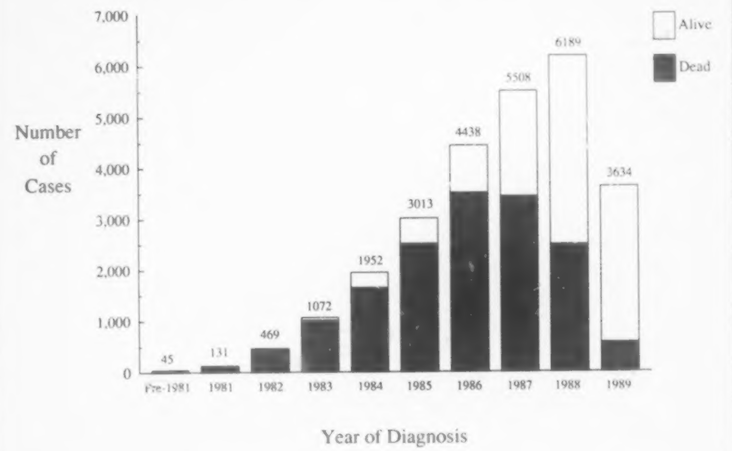

FIGURE 1—Number of AIDS cases (N = 26,576) by Vital Status and Year of Diagnosis, New York State

NOTE: A total of 125 cases with unknown vital status were excluded. Data for 1989 are incomplete due to the delay in case reporting.

adolescents (>12 years old) or children (<13 years old) and by hierarchical exposure groups, according to the CDC system.[9]

As a measure of HIV transmission among adolescents, data for persons 20–24 years old were analyzed. Adults in this age group are likely to have been infected during adolescence because of the long median incubation period for AIDS, which studies suggest is about 10 years.[10–12] Cases among teenagers were not included in this analysis, since their infections may have occurred before adolescence.

AIDS incidence rates were calculated with official New York State population projections by age, sex, and geographic region for 1985.[13] For race-specific population estimates, we applied the racial distribution from the 1980 Census to the 1985 projections, since race-specific projections are not available.

For comparison with results of the Newborn HIV Seroprevalence Study,[14] we used the incidence of AIDS per 100,000 women of childbearing age (15–49 years) during 1988. From the Newborn HIV Seroprevalence Study, we used data for all births to mothers in this age group in 1988. The data were stratified by age, race/ethnicity, and geographic regions, according to urbanization and proximity to New York City, as described elsewhere.[14]

Results

Cases by Type of Definition

A total of 26,576 cases of AIDS were reported statewide by the cutoff dates for this report, accounting for 23 percent of the 115,158 cases reported nationally. Of these cases, 22,186 (83 percent) met the pre-1985 national surveillance case definition,[3] 592 (2 percent) met the 1985 definition,[5] and 3,798 (14 percent) met the expanded 1987 definition.[6] Of the 1987 definition cases, 47 percent had indicator diseases that were diagnosed definitively; the rest were diagnosed presumptively. Of 9,847 cases diagnosed in 1988 and 1989, 29 percent met only the 1987 case definition (13 percent definitive, 16 percent presumptive). Of the total 26,576 cases, 16,163 (61 percent) had *Pneumocystis carinii* pneumonia, and 3,505 (13 percent) had Kaposi's sarcoma.

Incidence and Mortality

The number of AIDS cases diagnosed statewide has increased every year through 1988 (Figure 1). An estimated 90 percent of cases that are ultimately reported are included in the registry by 11 months after diagnosis (Dr. Lawrence Lessner, New York State Department of Health, personal communication). Because of this delay in reporting, the number of cases for 1989 is expected to exceed that for 1988 when reporting is complete.[15]

Of the 26,576 reported cases, 17,531 (66 percent) are known to have died as of the cutoff dates for this study. Thirteen percent of all cases died within one month of diagnosis. The case fatality rate is highest for cases with the longest follow-up: 90 percent of cases diagnosed before 1985. Of patients diagnosed before 1988, 80 percent have died (median survival time, 10.3 months).

Geographic Distribution

New York City accounts for 22,231 (84 percent) of all statewide cases, although the percentage has dropped as the epidemic spread. Another 3,250 cases (12 percent) were reported among the general population from New York State exclusive of New York City and 1,095 (4 percent) among prisoners in the state correctional system.

The geographic distribution of cases in quartiles is shown in Figure 2. Cases among prisoners are excluded, because accurate information on their counties of residence was not available. Although cases are widely distributed throughout the state, they tend to concentrate in counties with major metropolitan areas (e.g., Albany, Erie, Monroe, and Onondaga), as well as in New York City and nearby counties.

Gender

Males account for 22,482 (87 percent) of the statewide adult/adolescent cases (Table X-1). There is no difference in gender distribution between cases in New York City and New York State exclusive of New York City. The male case predominance reflects the large number of cases among men with a history of homosexual/bisexual contact. However, this percentage is lower than that for the rest of the United States, because New York State has a disproportionately high number of women who contracted AIDS by intravenous drug use.

Among children there is a slightly higher proportion of cases among males, but the gender distribution differs little from the rest of the United States (Table X-2).

Age

The age distribution of adult/adolescent cases statewide is similar to that in the rest of the United States, with nearly 90 percent of cases occurring among persons 20–49 years old (Table X-1).

Among children, New York State has 604 reported cases statewide and accounts for 31 percent of all such cases in the United States (Table X-2). Of these pediatric patients, 534 (88 percent) were

FIGURE 2—Cumulative number of AIDS Cases and Incidence per 100,000 Population since the beginning of the Epidemic, by County or Borough of Residence, New York State

NOTE: Cases among New York State prison inmates were excluded. Cumulative incidence was based on New York State Department of Commerce population projections for 1985.

residents of New York City. Compared with the rest of the United States a greater proportion of cases occurred among children under five years old, reflecting the greater proportion of children infected perinatally in this state.

Race/Ethnicity

Whereas Blacks and Hispanics account for 37 percent of adult/adolescent cases in the rest of the United States, they account for nearly 60 percent of such cases statewide (Table X-1). This difference reflects the large percentage of Black and Hispanic cases in New York City (62 percent) and in state prisons (85 percent). In New York State exclusive of New York City, Blacks and Hispanics account for 37 percent of cases.

The statewide cumulative incidence rate (per 100,000 population) from the beginning of the epidemic among adult/adolescent males is several times higher among Blacks (901) and Hispanics (1,029) than among Whites (183) (Table X-3). For females, the racial/ethnic disparity is even greater (Table X-4).

Of children with AIDS, nearly 90 percent statewide are Black or Hispanic, compared to 72 percent in the rest of the United States (Table X-2).

Exposure Groups

The AIDS epidemic among adults and adolescents has primarily affected two exposure groups: men with a history of homosexual/bisexual contact, and IVDUs. The epidemic curve for gay men has leveled off or declined in recent years (Figure 3).

In 1988, for the first time, more cases were diagnosed among IVDUs than among gay men statewide. The percentage of cases among IVDUs is greater statewide (39 percent) than in the rest of the United States (16 percent) (Table X-1). Of the 1,095 prisoners with AIDS, 957 (87 percent) gave a history of intravenous drug use without homosexual/bisexual contact. Even when prisoners are excluded, the percentage of cases with a history of intravenous drug use is still higher in New York City (36 percent) and in New York State exclusive of New York City (35 percent) than in the rest of the United States (16 percent). The percentage of

*Includes persons presumed to have become HIV-infected through heterosexual contact because they were born in countries where heterosexual transmission is believed to be the major mode of transmission.[9]

cases among non-IVDU men with a history of homosexual/bisexual contact was similar in New York City (49 percent) and New York State exclusive of New York City (44 percent).

The third most common exposure group is persons at risk for AIDS because of heterosexual contact. A slightly higher percentage of cases is in this category statewide than in the rest of the United States (5.4 vs 4.7 percent) (Table X-1). This category contains two subgroups: persons who report heterosexual contact with a person at risk for AIDS, and persons who are presumed to have become HIV-infected through heterosexual contact because they were born in countries where heterosexual transmission is believed to be the major mode of transmission, the so-called Pattern II countries.[9] Of the 1,390 statewide cases of heterosexual contact, 903 (65 percent) reported contact, and 487 (35 percent) were from Pattern II countries. Of the 903 cases with reported contact, 757 (84 percent) reported having sex with an IVDU.

The distribution of exposure categories varied by race/ethnicity and gender. Of all cases among White males, 78 percent were attributed solely to homosexual/bisexual contact, in contrast to 35 percent of Black and Hispanic males (Table X-3). Intravenous drug use was the leading exposure category for both Black (49 percent) and Hispanic (55 percent) males. Among females there was less variation, although heterosexual contact accounted for a larger percentage of cases among Blacks (27 percent) and Hispanics (34 percent) than among Whites (23 percent) (Table X-4). Overall the leading exposure categories for females were intravenous drug use (62 percent) and heterosexual contact with a person at risk for AIDS (25 percent). Of the 864 females in the latter group, 729 (84 percent) reported having sex with an IVDU.

Statewide, 91 percent of children with AIDS were classified as acquiring their infection from their mothers (perinatally), compared with 76 percent in the rest of the United States (Table X-2). This difference is largely due to the majority (59 percent) of pediatric cases statewide whose mothers used intravenous drugs.

AIDS among Young Adults

Statewide 867 AIDS cases were reported among persons 20–24 years old, of whom 251 (29 percent) were White, 298 (34 percent) were Black, and 309 (36 percent) were Hispanic; the remaining nine were of other or unknown race/ethnicity. The leading exposure groups for these cases were male homosexual/bisexual contact, 403 (46 percent); intravenous drug use, 248 (29 percent); male homosexual/bisexual contact and intravenous drug use, 40 (5 percent); heterosexual contact with an intravenous drug user, 64 (7 percent); and born in a Pattern II country, 29 (3 percent). The remaining 83 cases were attributed to other exposure categories.

Comparison of AIDS Data with Newborn HIV Seroprevalence

Two measures of HIV infection among women are shown in Table X-5: the incidence of AIDS per 100,000 women in 1988, and the rate of HIV seropositivity among women giving birth in 1988, based on data from the Newborn HIV Seroprevalence Study. The absolute rates of these measures varied because of the different events they reflect: onset of severe HIV disease and prevalence of infection among women giving birth. However, both measures showed comparable trends. The highest rates occurred among persons 20–39 years old, Blacks, Hispanics, and women residing in New York City. Both rates declined with distance from New York City. The only disproportionate trend was among persons 15–19 years old: a disproportionately lower rate of AIDS per 100,000 women relative to the older groups, compared with the HIV seropositivity rates from the newborn study.

Discussion

AIDS has become a major cause of morbidity and mortality statewide. It is the leading cause of death among men 30–49 years old and women 20–39 years old in New York City, as well as among persons 30–39 years old in minority racial/ethnic groups in New York State exclusive of New York City.[15]

Statewide the effect of the AIDS epidemic among IVDUs is apparent in its increasing toll on racial minorities, women, and children. Transmission of HIV by contaminated needles has disproportionately affected Blacks and Hispanics. Both intravenous drug use and heterosexual transmission from IVDUs have caused a greater proportion of cases among women here than in the rest of the nation, and these women have transmitted HIV perinatally to a large number of children.

AIDS surveillance data have complemented the information provided by the HIV seroprevalence studies. Whereas seroprevalence studies provide timely information on the number, geographic distribution, and changing characteristics of HIV infected persons, information from AIDS surveillance provides detailed information on each reported case since the beginning of the epidemic. AIDS surveillance data show patterns similar to those from the Newborn HIV Seroprevalence Study except for one age-group difference. Where the Newborn Seroprevalence Study shows an alarming rate of HIV infection among women 15–19 years old, surveillance data show that they have a low incidence of AIDS. This finding appears to reflect the long incubation period for AIDS. AIDS case data for persons 20–24 years old statewide suggest that HIV transmission among adolescents has occurred more frequently among Blacks and Hispanics than among Whites and that sexual contact (both homosexual and heterosexual) has been the leading risk behavior.

Other/Undetermined	43	(7.0)	143	(7.9)	46	(4.4)	242	(6.9)
Total	611	(100.0)	1,800	(100.0)	1,043	(100.0)	3,489	(100.0)
Cumulative Incidence per 100,000***	10.5		185.5		160.0		46.0	

*Included in the total are 13 cases whose race/ethnicity is American Indian, Alaskan Native, Asian, or Pacific Islander and 22 whose race/ethnicity is unknown.

**See Table 1.

***Incidence was calculated as the cumulative number of AIDS cases among females, age 15 years and older, since the beginning of the epidemic, divided by estimates for the female population, age 15 years and older, by race/ethnicity in 1985. (See text for details.)

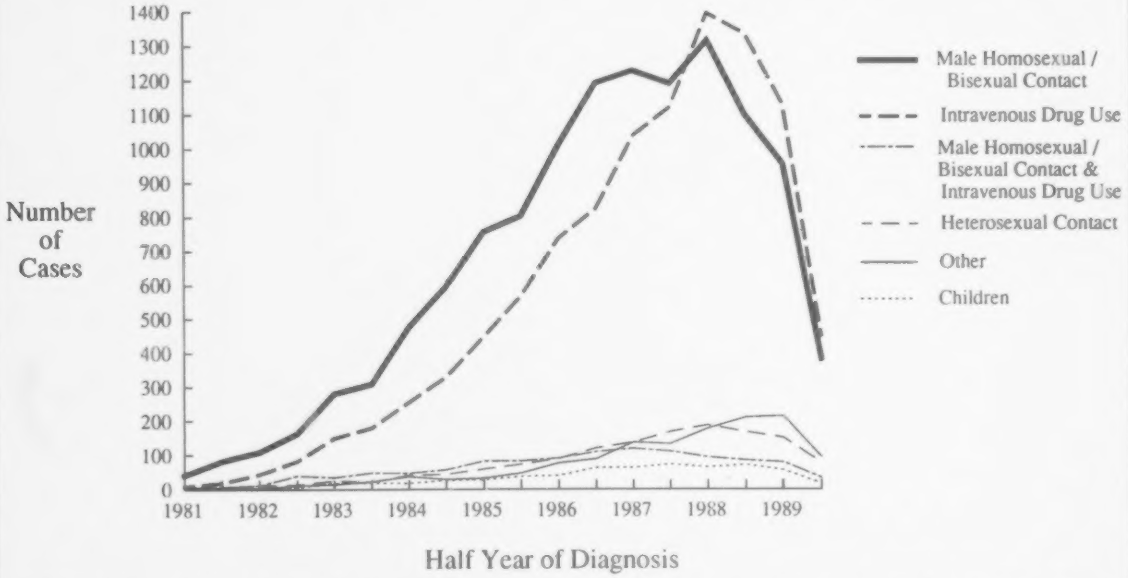

FIGURE 3—Number of AIDS cases among adult/adolescent exposure groups and among children by half-year of diagnosis, New York State

NOTE: Data for 1989 are incomplete due to the delay in case reporting.

The New York State DOH continues to monitor information from AIDS surveillance and the HIV seroprevalence studies to better address the needs of those already infected and to plan interventions that will limit the spread of HIV.

Summary

New York State has reported more AIDS cases (26,576) through November 1989 than any other state, accounting for 23 percent of all reported cases in the nation at the time. New York City has reported 22,231 (84 percent) of the statewide cases. The epidemiology of AIDS in New York State has been easily influenced by the large number of cases among IVDUs. Whereas intravenous drug use accounts for 16 percent of adult/adolescent cases in the rest of the nation,

TABLE X-5—Comparison of the Number and Incidence of Female AIDS Cases with HIV Seroprevalence among Women Giving Birth by Age Group, Race/Ethnicity, and Geographic Region in New York State 1988

Characteristics	Number of Cases and Incidence of AIDS per 100,000 Women in 1988 No.	Incidence*	Prevalence (per 100,000 Births) of HIV Seropositivity among Women Giving Birth in 1988** (N = 271,843)
Age Group (years)			
15–19	3	0.4	430
20–29	230	14.8	650

Total	900	19.1	630

*Based on the number of AIDS cases among women ages 15–49 years and the 1985 population projections for women of this age group in New York State.

**Based on newborn HIV seroprevalence testing.

it accounts for 39 percent of the cases in New York State. Intravenous drug use is the leading exposure category among racial minorities, with a disproportionately high rate of cases among Blacks and Hispanics. The epidemic among women and children has also been severe, resulting from intravenous drug use by women, heterosexual transmission from drug users to women, and perinatal transmission to their children. ☐

Acknowledgments

The authors gratefully acknowledge the AIDS surveillance staff of the New York State and New York City Departments of Health for data collection, Rachel Stricof and Michael Davisson for newborn seroprevalence data, and Lloyd Novick for manuscript review. Surveillance activities were partially supported with funding through cooperative agreements with the Centers for Disease Control.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription Price is $80/year US; $120/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

rence in the community . . .[1] of a group of illnesses of similar nature, clearly in excess of normal expectation." The attribution of this particular epidemic to the adverse effect of postaccident stress provides new and potentially important insights into the etiology of cancer and into the circumstances that may eventually need to be managed to better protect the public health. The idea that stress may be an environmental culprit could change many aspects of the way we handle acute environmental problems like the Three Mile Island accident. The way such environmental events are publicized and managed may need to be reconsidered if further evidence supports the conclusion that stress can cause or promote a disease like cancer. Studies of cancer incidence at the Love Canal before the problem was publicized in 1978 provided no clear evidence of increased cancer risks even though chronic exposure to environmental toxins had taken place over years and decades.[3] However, since the entire neighborhood surrounding the Love Canal was relocated at the time the problem of toxic exposure was publicized in 1978, it has not been possible to determine whether the stress associated with publicity surrounding that event might have lead to increased cancer rates in the years after 1978.

It will be important for public health officials to devise expanded research strategies for past and future environmental episodes that consider every plausible hypothesis for disease etiology. Latency periods prior to clinically apparent cancer may be very long. The promotion of already initiated cancer cells, through a stress-induced neuroendocrine mechanism, is not a far-fetched idea. Parenthetically, we should remember that only three or four decades ago many doubted that tobacco smoke could cause lung cancer and that the environmental pollution during an intense London fog in 1952 could have been responsible for some 4,000 deaths. As we consider the plausibility of the stress explanation in the report by Hatch et al., it is important to observe that a temporary promotion of cancer should lead to a short period of increased risk, followed by a compensatory period of decreased risk. The decreased risk occurs because new cancers are not initiated by a promotional event. Promotion can only hasten the progression of an existing cancer to the stage when the disease becomes clinically apparent. Perhaps mortality rates for cancer will need to be added to such studies.

The theories of initiation and progression of cancer are complex, but in general, a promotional event will not produce new cancers, although it may appear to do so in the short run. The data presented by the authors are consistent with such a pattern. As the authors clearly recognize, it is also difficult to rule out the possibility that increased clinical surveillance, perhaps stimulated by the same anxiety that produced the stress, could produce a short-term increase followed by a compensatory decrease in cancer cases diagnosed among the study population. The fact that the initial increase did not occur until three years after the nuclear accident lends more support to the promotion hypothesis than the increase-in-clinical-surveillance hypothesis as the explanation for this phenomenon. Whatever the final explanation for this cancer cluster following the Three Mile Island nuclear accident, the cluster underscores the need for more epidemiologically driven studies of major and minor environmental accidents. The investigators who conduct such studies should keep an open mind to the potential etiological mechanisms by which the circumstances around us may cause human diseases, including cancer. ☐

Erratum

In: Kahn HS, Williamson DF, Stevens JA: Race and weight change in US women: the roles of socioeconomic and marital status. Am J Public Health 1991;81:319–323.

The abstract was improperly copy edited by staff, resulting in the deletion of some important information in the Results section. The Results section of the abstract should read as follows:

"After multiple adjustments, Black race, education below college level, and becoming married during the follow-up interval were each independently associated with an increased mean weight change. Using multivariate logistic analyses, Black race was not independently associated with an increased risk of major weight gain (change $\geq +13$ kg), but it was associated with a reduced likelihood of major weight loss (change ≤ -7 kg) (odds ratio = 0.64 [95% CI = 0.41, 0.97]). Very low family income was independently associated with the likelihood of both major weight gain (OR = 1.71 [95% CI = 1.15, 2.55]) and major weight loss (OR = 1.86 [95% CI = 1.18, 2.95])."

The Journal regrets the error.

Asthmatic Responses to Airborne Acid Aerosols

Bart D. Ostro, PhD, Michael J. Lipsett, MD, JD, Matthew B. Wiener, PharmD, and John C. Selner, MD

ABSTRACT

Background: **Controlled exposure studies suggest that asthmatics may be more sensitive to the respiratory effects of acidic aerosols than individuals without asthma. This study investigates whether acidic aerosols and other air pollutants are associated with respiratory symptoms in free-living asthmatics.**

Methods: **Daily concentrations of hydrogen ion (H^+), nitric acid, fine particulates, sulfates and nitrates were obtained during an intensive air monitoring effort in Denver, Colorado, in the winter of 1987–88. A panel of 207 asthmatics recorded respiratory symptoms, frequency of medication use, and related information in daily diaries. We used a multiple regression time-series model to analyze which air pollutants, if any, were associated with health outcomes reported by study participants.**

Results: **Airborne H^+ was found to be significantly associated with several indicators of asthma status, including moderate or severe cough and shortness of breath. Cough was also associated with fine particulates, and shortness of breath with sulfates. Incorporating the participants' time spent outside and exercise intensity into the daily measure of exposure strengthened the association between these pollutants and asthmatic symptoms. Nitric acid and nitrates were not significantly associated with any respiratory symptom analyzed.**

Conclusions: **In this population of asthmatics, several outdoor air pollutants, particularly airborne acidity, were associated with daily respiratory symptoms. (*Am J Public Health.* 1991;81:694–702)**

Introduction

Exposure to acidic aerosols and sulfates has been associated with increased mortality and respiratory morbidity in a variety of settings.[1–5] Controlled exposure chamber studies suggest that individuals with asthma are more sensitive to the bronchoconstrictive effects of acidic sulfates than individuals without known pulmonary disease.[6–9] While the effects of exposure to ambient particulates (which may include acid aerosols) on asthmatic symptoms have been studied epidemiologically, previously published investigations have not included concurrent daily measurements of ambient airborne acidity.[4,5,10–12] Since the US Environmental Protection Agency has recently begun to consider whether to promulgate a national ambient air quality standard (NAAQS) for acid aerosols, it is important to assess the effects of relatively low levels of exposure on individuals in typical, free-living conditions. Thus, the need to extrapolate from studies of animals or of volunteers in controlled human clinical studies is obviated. In this study we report the results of an analysis of the association between ambient airborne acidity and daily respiratory symptoms recorded by a panel of asthmatics in Denver, Colorado during the winter of 1987–88.

Particulate air pollution has been associated with increased asthmatic symptoms and respiratory hospital admissions.[4,5,10–12] In an analysis of daily diaries of 454 asthmatics in the Los Angeles area, Whittemore and Korn[10] reported increased probabilities of attacks on days with high oxidant and total suspended particulate (TSP) pollution. Interpretation of this study is limited, however, by (among other things) the inadequacy of TSP as a measure of respirable particulate exposure and by significant covariation of TSP and ozone. Using a modification of the analytic model developed by Whittemore and Korn,[10,11] Perry, *et al*,[12] investigated the effects of fine (<2.5 microns in aerodynamic diameter) and coarse (>2.5 and <15 microns) particulates on respiratory symptoms, peak flows, and bronchodilator usage in 24 asthmatics in Denver in winter 1979. Fine nitrates were associated with increased symptoms and bronchodilator usage, while fine sulfates were associated with increased bronchodilator usage. The implications of this analysis are unclear because of the small sample size, the relatively low levels of particulate pollution, and the absence of acid aerosol measurements. In an ongoing study in Ontario, Canada, summer hospital admissions for asthma have been associated with exposure to ozone, sulfates, and sulfur dioxide.[4,5] These constituents of the "acid summer haze" were highly correlated; however, recent evidence[5] suggests that ozone may be less important than sulfates since there was a low correlation between respiratory admissions and ozone during one month of particularly high ozone concentrations. Again, acid aerosols were not measured.

The respiratory effects of airborne particulates on asthmatics and others have been attributed to the irritant, acidic frac-

Dr. Selner is with the Allergy Respiratory Institute of Colorado, Denver, CO. This paper, submitted to the Journal October 24, 1989, was revised and accepted for publication August 13, 1990.

TABLE 1—Characteristics of Patient Population Participating in the Denver Asthma Study

Characteristics	Total Study Population (n = 256)	Diary Participants (n = 207)
Mean age	44.3	45.6
% Male	34	34
Race (% White/Black/other)	94.6/2.3/3.1	96.5/1.5/2
Education (%)		
College	62	62
High school	37	37
Less than high school	1	1
Employment status (% employed outside home/homemaker/retired/other)	71/10/15/4	70/10.5/13.5/6
Mean subjective asthma severity rating (0 = none, 4 = incapacitating)	1.78	1.74
% Daily Theophylline	56.4	58.0
% Daily oral steroids	21.8	18.9
% Current smokers	3.1	3.0

tion of this heterogeneous mixture of pollutants.[13-15] In controlled chamber studies of healthy individuals and asthmatics, acidic sulfates (H_2SO_4 and NH_4HSO_4) have been associated with bronchoconstriction and increased bronchial reactivity.[6-9] In a study involving short exposures (30 minutes at rest followed by 10 minutes of exercise), Koenig, *et al*,[6] reported significant changes in flow rates and pulmonary resistance in adolescent asthmatics exposed to 100 $\mu g/m^3$ H_2SO_4. Some studies showed effects only at higher levels of exposure which exceed typical urban peak sulfate levels,[7-9] and some showed no effects.[16] Nitrates and nitric acid have been studied less than acidic sulfates. Overall, the results of chamber studies suggest that asthmatics may be an appropriate "sensitive population" to study epidemiologically in relation to airborne acidity.

An intensive daily air monitoring program in the metropolitan Denver area was conducted from November 1987 to February 1988 to investigate the chemical composition and particle size distribution of the winter "brown cloud." The Integrated Environmental Management Program of Region VIII of the US Environmental Protection Agency (EPA) conducted a complementary air monitoring program from November 1987 to March 1988. The joint monitoring effort included twice-daily measurements of particulates (sulfates, nitrates, and all particles less than 2.5 microns in diameter or PM2.5), airborne acidity, and sulfur dioxide at two sites. Aerosol acidity was measured using annular denuder instrumentation[17] and included nitric acid vapor and nanoequivalents of hydrogen ion (H^+) in particulate form, which was not further speciated (into H_2SO_4 or NH_4HSO_4). Meteorologic data were collected by the State of Colorado and by Stapleton Airport in Denver. This period of intense air monitoring provided an occasion to investigate whether exposure to fine acidic particulates is associated with respiratory effects in asthmatic individuals. No previously published epidemiologic studies have correlated concurrently measured airborne acidity with asthmatic symptoms and behavior.

Data and Methods

Study Population

Study participants were recruited from patients attending the clinic of one co-author (JCS). Diagnosis of asthma was made in each case by history and signs of airway obstruction on physical examination, confirmed by spirometric demonstration of obstruction reversible with a β-agonist bronchodilator (>15 percent change in FEV_1). Asthmatic patients were identified by clinic staff and were recruited for participation either during an office visit or by telephone and postcard contact. Denver residents between ages 18 and 70 were eligible to participate in the study if they had asthma currently managed with medication. Individuals with any other chronic medical condition that would restrict their activity were excluded.

This panel of asthmatics was asked to record, on a daily basis for several months, information about symptoms, medication use, utilization of medical services, indoor exposures, and other variables described below. In the context of the air monitoring efforts noted previously, a panel study has several advantages over other investigative designs. First, it provides a large number of observations, increasing the degrees of freedom and the stability of any estimates. Second, problems of confounding, omitted variables, and exposure assessment, while always present, are substantially reduced since individuals serve as their own controls over time. Thus, the impact of factors that vary daily, such as air pollution, can be isolated while other factors are held constant. Third, the consideration of a given sample in one metropolitan location over time eliminates the potential for any intercity confounding.

Health Measurements and Covariates

After giving informed consent, participants were required to fill out an intake questionnaire providing background data on demographics (age, sex, race, level of education, employment status, residential history), asthma severity and characteristic triggers and symptoms, medical history including medication use, smoking history, and previous environmental exposures. A diary instrument was designed to provide daily information on asthma symptoms, including the presence and severity on a scale of 0 to 4 (0 = none, 1 = mild, 2 = moderate, 3 = severe, 4 = incapacitating) of cough, wheeze, shortness of breath, chest tightness, and sputum production, as well as physician and emergency room visits. In addition, information was obtained on frequency of medication use, time spent outdoors, levels of exercise intensity and whether exercise occurred indoors or outside, indoor exposure to respiratory irritants (such as gas stoves, fireplaces, and environmental tobacco smoke), and occupational exposures. Participants were told that this was an investigation of environmental factors affecting asthma, but not that the principal variables of interest were air pollutants.

There were 330 intake questionnaires distributed (93 during office visits and 237 by mail) from November 15 to December 16, 1987. Of the initial group recruited, 256 returned the intake questionnaires. Study subjects were contacted by clinic staff intermittently throughout the study period (December 1987 through February 1988) to enhance compliance and continued participation. Two hundred and seven patients returned their daily diaries. There were similar distributions of demographic variables and asthma severity in the initial study population and those who returned the daily diaries (Table 1). The group un-

der study was predominantly White, female, employed, and well educated, with an average age of approximately 46. The mean subjective asthma rating of moderate to severe is supported by the relatively large proportion of individuals taking daily oral theophylline and steroid preparations.

Exposure Measurement

The ambient air pollutants incorporated in the analysis were daily measures of sulfates, nitrates, PM2.5, nitric acid, hydrogen ion (H^+), and sulfur dioxide. Two different pollutant averaging times were considered initially: the 24-hour average (ending at 4:00 pm on the reporting day) of pollutant readings from the monitor in downtown Denver, located about two miles from the clinic; and the daytime average (9:00 am to 4:00 pm) from the same monitor. Since these averaging times were highly correlated (usually $r > .90$), only the daytime average was used in subsequent analysis. A second monitor, located about seven miles away in the northwestern suburb of Arvada, also provided measurements of these pollutants. Table 2 provides descriptive statistics for the pollutant, meteorologic and health variables. We found no statistically significant relationship between any pollutant and either the number of the day of the survey period or whether the reading was on a weekday or weekend and no significant time trend for either daily minimum temperature or daily humidity.

There was substantial covariation among some of the pollutants; the highest correlations were observed between PM2.5 and sulfates ($r = .88$), and between nitrates and nitric acid ($r = .78$). Sulfates and H^+ were both negatively correlated with maximum daily temperature (Table 3). Of the pollutants measured on a daily basis, sulfates had the most complete data. Values for missing days of PM2.5 and nitrates were derived from stepwise regressions using all other pollutants. PM2.5 could be predicted well by concurrent values of sulfates and nitrates ($r = .97$), and nitrates could be predicted by nighttime (4:00 pm to 9:00 am the following day) PM2.5 readings ($r = .86$).

The data on H^+ required additional attention. Because of problems in sample processing, the H^+ data were available only for half of the study period. The first seven days of H^+ readings were extremely high, with a mean of 288 nanoequivalents per cubic meter (neq/m^3), versus a mean of 10.1 for the following 28 days. The hydrogen ion concentrations during the first seven days were also unrelated to any other pollutant or meteorologic variables, while during the next 28 days there was a correlation, as expected, between H^+ and sulfates ($r = .66$). Consequently, the first seven days were dropped from the subsequent analysis. For H^+, missing values for the entire survey period were predicted using regression results with concurrent sulfate as the explanatory variable. With these substitutions, the daytime mean of H^+ was 8.15 neq/m^3 or approximately 0.4 $\mu g/m^3$ measured as sulfuric acid, with the highest daily average of 44 neq/m^3. All subsequent analysis for H^+ combined actual and imputed values. The one-hour peak may be three to four times higher than this longer-term average. These levels are typical of urban areas.[18] Analysis of the two monitors recording H^+ indicated that the concentrations of airborne acidity were fairly evenly distributed throughout the Denver area; the daily correlation of the readings was 0.88. Thus, the one downtown monitor was used to represent daily levels of H^+. Ozone concentrations, which frequently are highly correlated with sulfates and acids in the summer, were essentially at background levels through the winter in Denver (i.e. the maximum one-hour concentration was 0.042 ppm) and do not correlate with H^+ concentrations.

Previous research[19,20] suggests that incorporating information on exercise and time spent outdoors will improve the estimate of exposure. Therefore, we developed a measure of exposure that involved the product of the ambient pollution level, the duration of exposure, the time spent indoors and outdoors, and the ventilation rates based on exercise level (i.e. ventilation rates of 7, 10, 25, and 40 liters per minute for resting, mild, moderate, or strenuous exercise, respectively). Since the actual time and duration of exercise was not recorded in the diary, it was assumed to occur during the day and to last for one hour. Hours outdoors and exercise levels were taken directly from the daily diary, while the penetration ratio of indoor to outdoor levels of H^+ of 0.3 was derived from the published literature.[21] This adjustment for exposure was crude but represents an improvement over simply using outdoor levels of air pollution. The extent of the reduction in measurement error (and improvement in exposure assessment) is specifically tested in the subsequent analysis.

All data from questionnaires, daily diaries, air quality, and meteorologic monitoring were coded and edited in a SAS format for analysis.

Statistical Methods

For this analysis, two different health outcomes were used as dependent variables in the multiple regressions: the probability of a respondent reporting on a given day a moderate (or worse) cough and the probability of reporting a moderate (or worse) rating of overall asthma status. The daily diary question regarding asthma status follows queries about the severity of wheezing, shortness of breath, chest tightness, and sputum production and should, therefore, reflect the respondents' subjective overall ratings of their individual asthma symptoms. As a daily average, 16.33 percent of the respondents (range 7.4 to 30.6 percent) reported a moderate or worse asthma day and 15.1 percent (range of 7.4 to 32 percent) reported a moderate or worse cough (see Table 2).

We estimated effects on each health outcome using ordinary least squares regression models. Variables included in each regression were minimum daily temperature, and binary variables indicating daily use of a gas stove and if the response occurred on a weekend. Since reporting of symptoms decreased during the course of the study, we also included the time since the start of the study. The probability of a symptom on the previous day was included as an explanatory variable in light of previous reports.[10,11] Daily relative humidity was examined and eliminated from the model after it was consistently found to be unrelated to any of the health outcomes, as were several time-invariant variables such as sex and education. Each pollutant's effect on health was estimated by entering it separately into the regression equation.

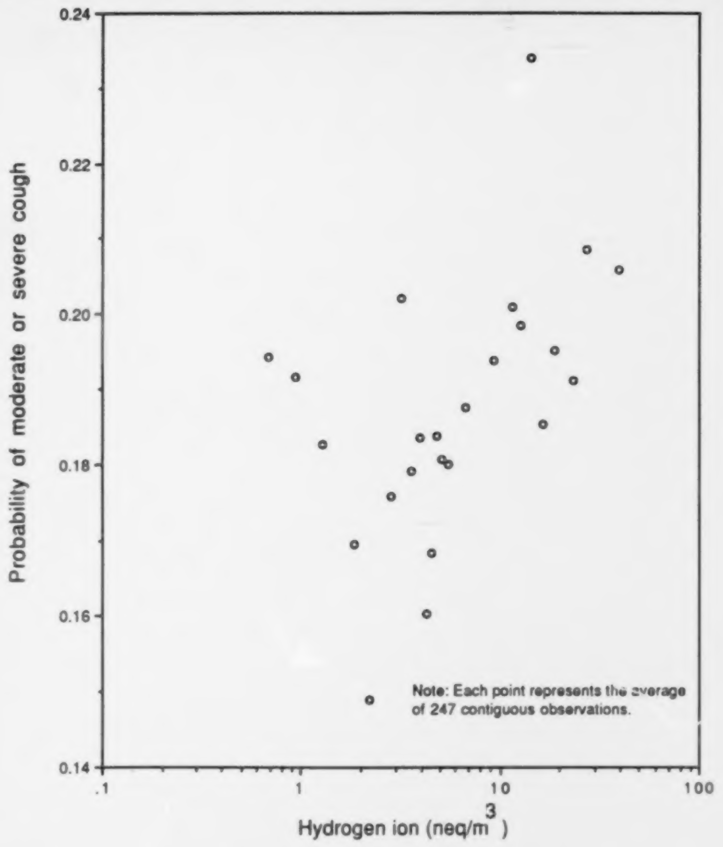
We also fitted a linear model of outcome using the logarithm of the pollutant, and a logistic model. There was little difference in model fit across the functional forms, but the log value of pollution provided the greatest association with the health outcomes. Thus, ordinary least squares with a log pollution term was used throughout the analysis. The similarity of results between ordinary least squares and logistic models probably was due to the relatively high rates of symptom incidence.

Significant autocorrelation was present, leading to biased estimates of the standard error of the estimated coefficients, and incorrect tests of significance.[22] The standard correction for autocorrelation involves estimation of a parameter (ρ) relating the regression residual at time t, r_t, to the residual for the previous time interval, r_{t-1}. When this feature is added to the estimation, the new model will have adjusted residuals which are uncorrelated. However, in this case, the procedure is biased and inconsistent because a lagged dependent variable (probability of symptom of the previous day) is included as an explanatory variable, and is correlated with the error term. Thus, the two-step procedure suggested by Fuller[23] was used. First, a predictive model was developed for the lagged value of the health effect (y_{t-1}) by regressing it on several independent variables, including time since start of the survey, specific air pollutants, minimum daily temperature, and humidity. Then the predicted value of y_{t-1} was used as an instrumental variable along with the other explanatory variables in the regression equation for y_t. Since the predicted value of the lagged dependent variable is uncorrelated with the adjusted residuals, the estimates are consistent. The estimation was performed using Proc Autoreg in SAS[24] with a maximum likelihood procedure that estimates both the regression coefficient and the autoregressive term.

Additional sensitivity analysis was conducted on the data, including a test for the influence of extreme observations, examination of other respiratory symptoms, and utilization of the exposure-adjusted measure of air pollution described above.

Results

Table 4 provides the ordinary least squares regression results for H^+, with the correction for autocorrelation. In the first two models, the dependent variables are the probability (×100) of reporting moderate or severe cough, and the probability of a moderate or worse asthma rating, respectively. The results indicate a statistically significant relationship between H^+ concentration and cough ($p < .01$) but not with overall asthma rating. Approximately 40 percent of the variation in the



Note: Each point represents the average of 247 contiguous observations.

FIGURE 1—Association of Moderate or Severe Cough with Hydrogen Ion

probability of reporting these symptoms was explained by the regression. For both cough and asthma status, reporting that symptom on the previous day was significantly related ($p < .0001$) with reporting a moderate or worse symptom. For cough, the day of the survey, responding on a weekend, and using a gas stove were statistically significant. Using overall asthma rating as the dependent variable, the only other significant risk factor (besides symptom on previous day) was usage of a gas stove ($p < .001$). For both cough and asthma status, autocorrelation corrections were appropriate and a second-order autocorrelation model was indicated. Figure 1 displays a plot of the relationship between hydrogen ion and moderate or severe cough.

Next, models with exposure-adjusted measure of H^+ were examined (Table 4). These models adjust outdoor air pollution levels for daily exercise levels and time spent outdoors. The results indicate that the exposure-adjusted measure of H^+ had a statistically significant association with both moderate cough ($p < .05$) and general asthma rating ($p < .10$). Figures 2 and 3 display these relationships.

Additional models correcting for autocorrelation were examined for each of the other pollutants, including sufates, sulfur dioxide, PM2.5, PM2.5 with substitutions for missing values, nitrates, and nitric acid. Each pollutant was considered individually and regressed first on cough and then on asthma rating and on shortness of breath. The other explanatory variables used in the multiple regression were those used above. Thus, Table 5 gives the results of these 18 separate regressions, each with one pollutant included in the equation. For comparison, the previous results for H^+ and exposure-adjusted H^+ are also included in the table.

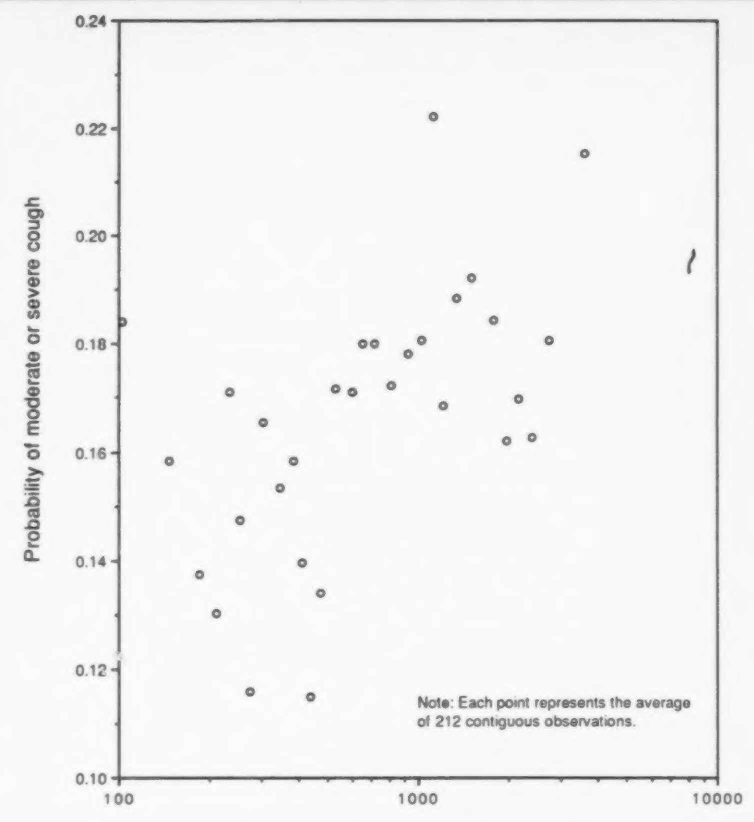
The results suggest that H^+, besides being associated with cough and overall subjective asthma rating, is also related to the reporting of moderate or worse shortness of breath. Besides H^+, the only other associations between individual air pollutants and these symptoms include: 1) sulfates and the probability of reporting moderate or worse shortness of breath ($p < .05$); and 2) PM2.5 and asthma rating ($p < .10$), after substitutions for missing values of PM2.5 were made, increasing the study duration from 46 to 75 days. Sulfur dioxide, nitrates, and nitric acid were not associated with moderate cough, asthma, or shortness of breath. The results for pollutants other than H^+ did not change when exposure-adjusted measures were used.

Additional analyses of the relationship of H^+ and asthmatic symptoms were conducted. The sensitivity of the models to the influence of extreme observations was tested using statistics proposed by Belsley, *et al.*[25] The test indicated that only the data from day = 2 had a relatively large influence on the regression results. The autoregressive model was rerun with that observation deleted, resulting in estimated regression coefficients that were essentially unchanged. Next, one- and two-day lags in H^+ were examined, indicating that contemporaneous measures of pollution provided the best association with asthma status. Finally, several time-invariant factors including education, sex, and whether an individual was recruited through office visit or by telephone were individually examined in the regression model. Their inclusion did not alter the estimated pollution effects.

Discussion

This analysis tested for an association between respiratory symptoms and several different air pollutants in a group of generally moderate to severe adult asthmatics. The results indicate a statistically significant association between ambient concentrations of hydrogen ion and the proportion of the subjects reporting moderate or worse cough and shortness of breath, with a lesser association observed in relation to the study subjects' overall asthma rating. Several lines of statistical and biomedical evidence implicate hydrogen ion as the principal pollutant of concern. First, although hydrogen ion was moderately correlated with minimum temperature and humidity (see Table 3), neither of these potentially confounding meteorologic variables was associated with the respiratory effects under investigation. Thus, it is unlikely that the estimated effects of hydrogen ion should be attributed to meteorologic changes over the survey period.

Second, confounding due to exposure to ambient ozone, which may cause



Note: Each point represents the average of 212 contiguous observations.

FIGURE 2—Association of Moderate or Severe Cough with Exposure-Adjusted Hydrogen Ion

exacerbations of asthma, was not a factor here. In studies linking health effects in asthmatics with resulting from summer haze in Southern Ontario[4] and particulate matter in Los Angeles,[10] ozone was highly correlated with the particle measure used in each study (sulfates and total suspended particulates, respectively), which in turn could be a surrogate for acid aerosol. In the Denver winter of 1987–88, ozone was generally found at background levels, as expected, with a maximum hourly concentration of 0.042 ppm.

Third, sensitivity analysis indicates that the findings were robust to functional form, specification, and influential observations. Linear and logistic functional forms provided similar results, and the estimated effect of air pollution was not affected by the exclusion of influential observations. In addition, the regressions were corrected for autocorrelation. Therefore, the results of the above analysis indicate that the symptoms reported are not likely to be due to a statistical anomaly.

The estimated impact of air pollution is greater when an adjustment for actual exposure is undertaken. For example, as indicated in Table 4, after adjusting exposure for intensity and location of exercise, time spent outdoors, and penetration rate of H^+, the estimated effect of air pollution on cough is 43 percent greater than that obtained from the unadjusted pollution measurements. This suggests that dose-response estimates for H^+ that do not incorporate behavioral factors affecting actual exposures may seriously underestimate the impact of air pollution.

Evidence from controlled exposure studies supports an etiologic role of hydrogen ion exposure in evoking asthmatic symptoms. Increasing sulfate aerosol acidity enhances the bronchoconstrictive effects in asthmatics in rough proportion to the acidity.[7] Exposure to 75 $\mu g/m^3$ of the nonacidic respiratory irritant, ferric sulfate, did not cause adverse effects on pulmonary mechanics or respiratory symptoms in normal or asthmatic subjects.[26] More recently, Fine, *et al*,[27] showed that buffered acid aerosols were significantly more potent bronchoconstrictors than unbuffered acids at the same pH, suggesting that the total available hydrogen ion is a critical determinant of airway responsiveness. The relationship between asthmatic symptoms and pulmonary function changes due to acid exposure is not clear-cut; however, some studies indicate that symptoms (especially cough) precede accompanying changes in respiratory mechanics, although this has not been consistently observed.[27–29]

This study suggests that hydrogen ion is the pollutant of primary concern. Although both sulfates and hydrogen ion were significantly related to the probability of reporting moderate or worse shortness of breath, only exposure-adjusted hydrogen ion was associated with the probability of reporting both a moderate or worse cough and asthma rating. Concentrations of particulate matter less than 2.5 microns were mildly associated with overall asthma ratings, but not with either cough or shortness of breath. Supporting evidence comes from a study of both asthmatics and healthy individuals,[30] in which ambient sulfates were not associated with acute respiratory symptoms, but airborne pH levels were. The importance of hydrogen ion over total sulfates or particle mass has also been suggested by the US EPA.[31] Since sulfate and particle measurements may include both acidic and nonacidic exposures, they incorporate measurement error which would bias downward the estimated regression coefficients and level of significance.

Of additional interest is the lack of association between nitrates or nitric acid and respiratory symptoms. Limited data from controlled chamber studies suggest that brief (10–16 min) exposure to high concentrations (up to 1,000 $\mu g/m^3$) of inorganic nitrate ($NaNo_3$) aerosols do not evoke respiratory symptoms or changes in pulmonary function in mild asthmatics.[32,33] Thus, there is some (admittedly sparse) clinical evidence to support the notion that particulate nitrates *per se* would not be expected to cause the effects reported here.

Our findings ostensibly conflict with those of Perry, *et al*,[12] who reported a mild association between respiratory symptoms and nitrates, but not sulfates, in a sample of 24 asthmatics. There may be at least three reasons for this discrepancy. First, the small sample size limits the generalizability of their findings. Second, the

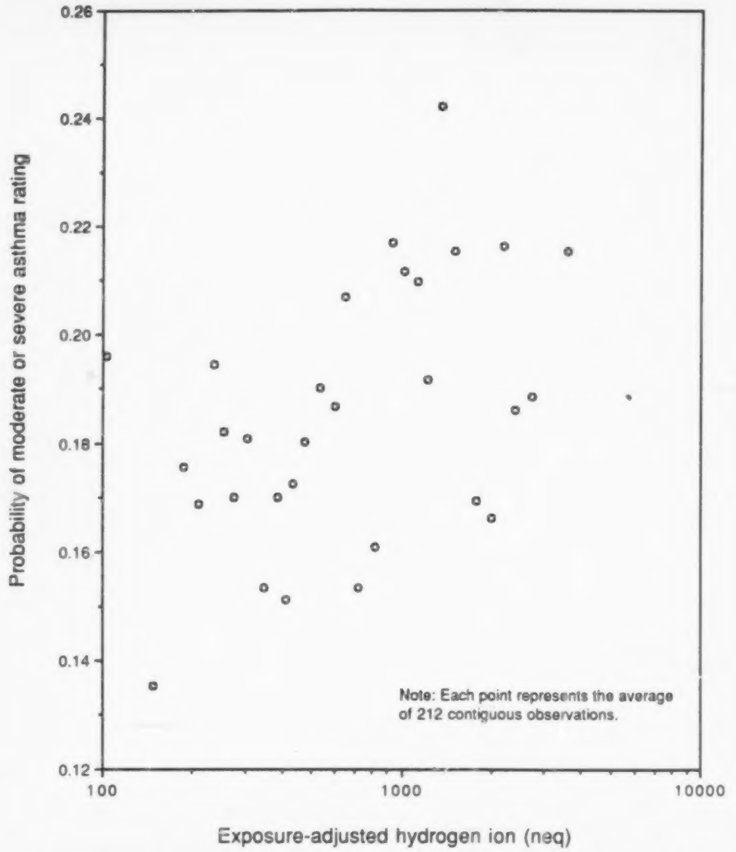


FIGURE 3—Association of Moderate or Severe Asthma Rating with Exposure-Adjusted Hydrogen Ion

rate of respiratory symptom reporting in that investigation was very low relative to ours. Third, there is a difference in pollutants under consideration and their dispersion patterns. Perry, *et al*, measured nitrates, sulfates, sulfur dioxide, and PM2.5 but not acid aerosols. In the Perry study and the present study the correlations among sulfates, sulfur dioxide, PM2.5, and temperature were remarkably similar, but nitrates were less correlated with other pollutants in the present study. This suggests that the sources of nitrates may have been quite different. Prior to the use of nylon back-up filters in the mid-1980s, nitrates were commonly measured inaccurately. Population growth and changes in automobile travel patterns also may have led to a change in exposures. In addition, during the winter of 1987–88, the major electric utilities, as part of a clean air campaign, burned natural gas instead of coal for alternate 15-day periods. These factors may have altered the dispersion pattern of nitrates, relative to sulfates and other pollutants, and the subsequent exposures of residents of the metropolitan area.

Since only about half of the individuals in this study completed their diaries every day, we investigated the potential for bias due to variable daily response rates. We found no relationship between air pollution and the number of people responding on a given day. We also investigated whether health status influenced response rates and found no relationship between overall severity of asthma and the number of days that people filled out the daily diaries. We infer that responses recorded in the daily diaries represent those of the group as a whole.

In this study population, the products of gas consumption appeared to exacerbate asthmatic symptoms. Peak indoor exposures to nitrogen dioxide (NO_2) resulting from gas stove use have been reported to range from 0.2 to 1.7 ppm,[34] which includes concentrations at which effects on symptoms or bronchial reactivity in asthmatics have been reported.[35,36] The concentrations of NO_2 and other constituents of natural gas combustion were not measured, but it is plausible that some symptoms were attributable to such indoor exposures.[37]

The results of this study, while supporting an association between asthmatic symptoms and ambient hydrogen ion exposure, should be interpreted with caution since pollutant measurements from fixed-site monitors cannot accurately represent individual exposures. Further, asthmatics may change their activity or medication use in order to reduce or eliminate symptoms related to air pollution; this would reduce the estimated effect of air pollution. Adjusting the pollution exposures for exercise and time outdoors increased the magnitude and precision of the estimate.

This study has several strengths, including the prospective nature of the investigation, the relatively large sample size, and the screening of the survey participants. Unlike previous large-scale studies of asthmatics, the sample for this study was recruited from one private practice at one location. Medical and personal histories were fully documented. Since the study was conducted as a time-series in one city over a relatively short period of time, geographic confounding factors were minimized, as was potential confounding due to ozone exposure. Relevant airborne acidity data, never previously collected concurrently with asthmatic symptom data, were also available.

This study provides evidence from a free-living population that is qualitatively consistent with the results of several controlled clinical investigations. Furthermore, our analysis indicates that, among moderate to severe asthmatics, respiratory symptoms occur at average hydrogen ion concentrations substantially lower than those at which effects on pulmonary mechanics have been observed in the laboratory.[7,9,28,29] That we were able to detect acute symptoms at the ambient concentrations measured was somewhat surprising. However, the study population was in general more severely afflicted than asthmatics volunteering for chamber studies. Some patients with severe asthma are known to have airway mucus with low pH, which may increase their susceptibility to acidic environmental insults.[38] Furthermore, the Denver winter temperatures and low relative humidity may have potentiated the effects of the airborne acidity (although we did not observe any obvious independent or interactive effects of these factors in the regression analysis). Cold dry air has been reported to enhance

TABLE 5—Estimated Regression Coefficients, Corrected for Autocorrelation, for Pollutants Examined Individually (standard error in parentheses)

bronchoconstriction caused by sulfur dioxide in one of the few experiments investigating interaction between physical and chemical exposures.[39] In other contexts, observational studies have found air pollution effects at concentrations below those at which chamber studies reported positive results.[40] This suggests that factors that are typically not included in chamber studies may play an important role in determining individuals' responses to air pollution. ☐

Acknowledgments

The authors would like to thank Steve Arnold of the Colorado Health Department, Mark Komp, Ken Lloyd, Steve Frey, and Robert Stevens of the US Environmental Protection Agency, and Suzy Rothschild of E. H. Pechan & Associates for assistance in collection, preparation, and quality control of air monitoring and health effects data. We would also like to thank Petros Koutrakis of the Harvard School of Public Health for supplying additional annular denuders.

An earlier version of this paper was presented at the 82nd Annual Meeting of the Air Pollution Control Association, June 1989.

Homeless Mentally Ill Will Benefit from Research Demonstration Projects

A unique collaborative effort to improve housing and services for homeless people who have a severe mental illness was announced recently by Health and Human Services Secretary Louis W. Sullivan, MD. The Department of Housing and Urban Development will join with HHS in supporting six research demonstration projects, each of which will combine housing assistance with mental health services.

The new projects will be carried out in five cities across the country and will be administered by the National Institute of Mental Health.

According to previous NIMH-sponsored research, one third of the homeless population has severe and persistent mental illnesses, including schizophrenia and mood disorders. Yet with adequate housing, treatment and support, most of these individuals can lead productive lives in the community.

NIMH funding for the new projects will be approximately $5.8 million in FY 1991 out of a planned total of $16.8 million over the next three years. HUD will contribute over $10 million in housing assistance. Projects will be located in Boston, Massachusetts; San Diego, California; Baltimore, Maryland; Cincinnati, Ohio; and two in New York City. In *Boston,* the project will evaluate two alternatives to housing homeless mentally ill individuals; consumer-managed group homes and independent living arrangements will be compared to determine which approach results in better housing stability with higher levels of functioning.

In *San Diego,* the research demonstration project will evaluate the effectiveness of linking comprehensive services to independent housing for severely mentally ill homeless persons.

In *Baltimore,* the project will test an "assertive community treatment" program designed to increase the clients' access to housing, as well as general health and mental health services.

The project in *Cincinnati* will compare the benefits of transitional housing and permanent housing.

In *New York City,* one research demonstration project will help individuals on the street obtain housing, such as single-room occupancy units, made available through a city/state agreement, while another project will be directed at mentally ill men who are preparing to leave a homeless shelter.

A Randomized Trial to Evaluate the Risk of Gastrointestinal Disease due to Consumption of Drinking Water Meeting Current Microbiological Standards

Pierre Payment, PhD, Lesley Richardson, MSc, Jack Siemiatycki, PhD, Ron Dewar, MSc, Michael Edwardes, PhD, and Eduardo Franco, PhD

ABSTRACT

Background: This project directly and empirically measured the level of gastrointestinal (GI) illness related to the consumption of tapwater prepared from sewage-contaminated surface waters and meeting current water quality criteria.

Methods: A randomized intervention trial was carried out; 299 eligible households were supplied with domestic water filters (reverse-osmosis) that eliminate microbial and chemical contaminants from their water, and 307 households were left with their usual tapwater without a filter. The GI symptomatology was evaluated by means of a family health diary maintained prospectively by all study families over a 15-month period.

Results: The estimated annual incidence of GI illness was 0.76 among tapwater drinkers compared with 0.50 among filtered water drinkers ($p < 0.01$). These findings were consistently observed in all population subgroups.

Conclusion: It is estimated that 35% of the reported GI illnesses among the tapwater drinkers were water-related and preventable. Our results raise questions about the adequacy of current standards of drinking water quality to prevent waterborne endemic gastrointestinal illness. (*Am J Public Health.* 1991;81:703–706)

Introduction

It has long been considered that water disinfected at 0.5 mg/L of free residual chlorine for 30 minutes at a pH less than 8, with a turbidity of less than 1 NTU would constitute minimal health risk to consumers.[1] Recently, however, increasingly sensitive analytic methods have permitted the detection of viruses[2] and parasites[3] in water meeting current water quality standards. This and several reported outbreaks of viral and parasitic diseases of waterborne origin[4] have prompted a review of the safety of current standards.[5] The suggested standards are based on the absence of fecal coliform bacteria in drinking water, fecal coliform bacteria being indicators of fecal pollution, and the ensuing risk of the presence of pathogenic microorganisms. The absence of total coliform bacteria in a majority of the samples collected is also recommended as an indicator of treatment efficiency.

While the current microbiological standards of water quality have virtually eliminated explosive outbreaks of waterborne disease,[6] there is no assurance that populations consuming drinking water prepared from sewage-contaminated wastes are free of less virulent gastrointestinal (GI) disease. While studies have addressed the health effects of recycled wastewaters[7,8] or of substandard drinking water,[9] all have relied on cases reported to the health care system to evaluate potential health effects. Other studies have addressed the health risks associated with chemicals in water or with disinfection byproducts.[10]

The present project was intended to directly and empirically answer the following question: Is there any measurable excess of GI illness related to the consumption of tap water prepared from sewage-contaminated surface waters and which meets current microbiological and physico-chemical water quality criteria?

Methods

Study Area

The study was carried out in a suburban area of Montreal comprised mainly of French Canadians with socioeconomic and education levels similar to the average of the Metropolitan Montreal area. The residents of this area are served by a single water treatment plant, which uses state-of-the-art treatment with pre-disinfection, flocculation by alum, rapid sand filtration, ozonation, and final disinfection by chlorine or chlorine dioxide. The raw water to be treated is drawn from a river which is mainly contaminated by human sewage discharges with little contamination from chemicals. The distribution system serves a population of about 40,000 people and distributes water meeting current microbiological and physico-chemical water quality standards.[5] A pilot study had shown that over 90 percent of the population drinks unmodified tap water and that the water was considered by the consumers to be of good to excellent quality.

Study Design

In order to determine the level of gastrointestinal illnesses attributable to drink-

ing water, we carried out a randomized trial in which some households were left with their usual tap water and others were supplied with a domestic water filter which eliminates most chemicals and all particulate and microbiological matter from the tap water.

The sampling process was undertaken to enroll approximately 600 households for study, half randomly assigned to the filtered water group and half to the tap water group. Using a directory of inhabited addresses for the study area, households were selected at random and telephoned in random order. A screening questionnaire served to determine whether the household satisfied the five eligibility criteria: 1) owner-occupied; 2) French-speaking occupants; 3) regular consumers of tap water (as opposed to bottled or filtered water); 4) at least one child between the ages of 2 and 18 living in household; 5) willingness to participate in a longitudinal trial in which a random half of the households would have a filter installed. A total of 3,741 households were contacted before we achieved our quota of eligible study households. After randomization, there were 299 families in the filtered water group (1,206 individuals) and 308 families (1,201 individuals) in the tap water group.

The selection of eligible families was completed in January 1988 but the full-scale morbidity follow-up started in March 1988 after all filtration units had been installed in the appropriate households. Health outcomes of interest were monitored until June 1989. Because of the difficulty of monitoring during the summer vacation period there was a two-month gap in the surveillance during July and August 1988. We will refer to the March 1988 to June 1988 observation period as Period 1, and September 1988 to June 1989 as Period 2.

Intervention

For the tap water group participants, there was no intervention and no suggestion to modify their normal water consumption patterns.

For the participants allocated to the filtered water group, under-the-sink filtration units were installed by professional plumbers, at no expense to the family, during the start-up period of February-March 1988. The filters were commercial domestic reverse-osmosis units attached to the cold water line and placed under the kitchen sink. They were composed of a prefilter, an activated charcoal filter, a reverse osmosis membrane cartridge, and a 15-liter reservoir containing the purified water. During the reverse-osmosis process, tap-water is forced through a molecular filter which is permeable only to very small molecules such as water and some inorganic salts. Microorganisms, particulates, and most chemicals are rejected by the membrane and discharged to the drain. The filters were obtained, installed, and maintained by a local supplier. Prefilters and charcoal were changed after nine months of use or upon clogging. Efficiency of the units was monitored weekly by the family informant using a small conductivity tester. Water in the reservoir of such units is pressurized by the water pressure of the main inlet to the house and is available at all times in sufficient quantity for normal usage by the whole family.

Background Information and Health Outcomes

All participating households were initially visited in January and February 1988 by a nurse who carried out an interview on baseline factors and explained the way the health data would be collected. The baseline data included sociodemographic and medical history information on each household member. The health end-point of interest was GI symptomatology and this was determined primarily by means of a family health diary maintained prospectively by all study families for the whole period except for the two-month summer break. A simple self-administered questionnaire was designed to be completed in two-week blocks. One household member, usually the female head, was designated as the informant. The informant was responsible for noting for any household member on each calendar day each incident of the following events: nausea, vomiting, or diarrhea (soft or liquid). If any of these three symptoms was recorded, the presence of the following accompanying symptoms was to be noted: fever, cramps, muscular pain, cold or flu, sore throat, absence from work or school, visit to a doctor, or hospitalization. For any positive reports, we inquired as to possible reasons such as food overindulgence, pregnancy, and visits to countries with high endemic levels of GI illnesses. At the end of each two-week period, a nurse from our staff telephoned the informant and asked for the information recorded on the diary. The regular and frequent contact by our staff was intended to encourage reporting accuracy.

For the purpose of statistical analyses reported here, we defined an episode of highly credible GI (HCGI) symptoms as involving at least one of the following combinations: 1) vomiting or liquid diarrhea with or without confinement to bed, consultation with a doctor, or hospitalization, or 2) nausea or soft diarrhea combined with abdominal cramps with or without absence from school or work, confinement to bed, consultation with a doctor, or hospitalization. Episodes with plausible etiologies apart from the one under study (e.g. pregnancy) were excluded from consideration. An episode was further defined as consisting of one or more symptomatic days, with at least six consecutive symptom-free days between the episodes.

Statistical Analyses

Outcome parameters included the percentage of study subjects with episodes, the annual incidence of episodes and the duration of episodes. The study subjects can be seen as the family units or as the individuals within these family units.

Some analyses were crude and thus included no other covariates apart from group membership while others included covariates to adjust for some imbalance in the two groups. The covariates included in the model, in addition to tap water/filter water status were: age, sex, and geographic subregion. Estimates of incidence of HCGI illnesses in the two groups were derived by means of Poisson regression methods.[11] Since this technique counts each episode as an independent event, a correction had to be made for the correlation between repeat episodes by the same unit of observation. This was done using the "quasi-likelihood" approach,[12] which amounts to reducing the nominal significance of each result by a factor related to the amount of this correlation. Adjusted rates were estimated from the results of the fitted model. Each regression model gave an estimate of the p-value associated with the parameter for group membership. The preventable fraction of disease was computed by dividing the difference in rate between the tap water and filtered water by the rate in tap water group. The percentage of subjects with episodes over some period of time was estimated by two methods, logistic regression, and proportional hazards analysis. Both of these techniques are based on data relating to the first episode that the individual experienced during the period of observation; the number of episodes experienced is ignored. The logistic regression analysis[13] requires that the period of

TABLE 1—Distribution of Selected Individual Characteristics in the Two Study Groups at the Study Outset

	% in Group:	
Sub-groups	Filtered Water (N = 1206)	Tap Water (N = 1202)
Age group		
0–5	9.6	6.2
6–20	37.4	39.4
21–49	46.0	43.2
50+	7.0	11.2
Sex		
Female	49.4	49.5
Male	50.6	50.5

NOTE: There were some dropouts during the course of the study. The total sample sizes at the beginning of the second period were 1,194 in the filtered water group and 1,067 in the tap water group. The distributions of characteristics were almost identical in the second period to those shown above in the first period.

observation be equal for all study subjects. Thus this analysis had to be limited to subjects for whom there were no missing data during the entire field work period. However, this analysis provided estimates of percentages of study subjects in both study groups who had at least one episode. The proportional hazards analysis by contrast can use all study subjects irrespective of the length of observation period but it estimates a rate ratio rather than a pair of rates.[14]

Water Consumption

To evaluate whether subjects in the two study groups were in fact consuming the type of water we intended them to consume, we carried out a survey to estimate each person's water consumption habits during one week day and one weekend day in the preceding seven days. This questionnaire asked about water consumed inside and outside the home and listed different types of use (e.g. straight, in juice, in hot drinks). From this survey, we computed an estimate of weekly water consumption inside and outside the home for each person. The response rate to this supplemental self-administered questionnaire was 82 percent among tap water subjects and 84 percent among filter water subjects.

Microbiological Analysis of Water

Water from the filtration plant (raw and treated) from 25 sampling sites in the distribution system and filtration units was sampled at least weekly for bacteriological and physicochemical analysis. The bacteriologic parameters estimated were: heterotrophic plate counts at 20°C and 35°C, total coliforms and fecal coliforms; *Clostridium perfringens, Aeromonas hydrophila, Pseudomonas aeruginosa.* Large volume virological analysis of the raw and treated water from the plant were also performed at least weekly according to the methods described previously.[15] Physicochemical parameters evaluated were: pH, turbidity, and residual disinfectant concentration. All analyses were performed by the Montréal Laboratory of the Ministry of Environment of Québec according to *Standard Methods for the Examination of Water and Wastewater*[16] and to the Ministry recommendations.[17]

Results

Water Quality

River water used for the preparation of the drinking water was contaminated by fecal material of human origin as indicated by the high levels of the following pathogens and indicator microorganisms found in the raw water entering the plant: human enteric viruses (78 viruses/100L), total coliforms (57,530 cfu/L), fecal coliforms (3,674 cfu/L), *C. perfringens* (623 cfu/L), *A. hydrophila* (6,590 cfu/L), and *P. aeruginosa* (41 cfu/L). Treated water (tap water) at the filtration plant was free of any detectable indicator bacteria and free of human enteric viruses and in compliance with regulations. However, bacterial growth was observed in the water filtration units as previously reported.[18]

Study Population Characteristics

Table 1 reports the age and sex distributions of the two study groups at the study outset. By and large, the randomization produced very similar groups, although there were slightly more very young and fewer very old in the filtered water group than in the tap water group.

Over 95 percent of eligible families maintained their participation for Period 1 (Table 2). For the entire two periods, the participation rates were 86.0 percent in the tap water group and 92.6 percent in the filtered water group.

Water Consumption

Table 3 shows that at home the two groups consumed about the same amount of water, the tap water group consuming only tap water and the filtered water group consuming almost entirely filtered water. Away from home, both groups consumed mainly tap water and in both groups there was about five times as much water consumed at home than outside the home.

Disease Outcome

During the study period there were no outbreaks of gastrointestinal diseases officially reported to the local health authorities. The number of visits to physicians for gastrointestinal symptoms and of hospitalizations was similar in both groups.

Altogether 65 percent of families experienced at least one episode of HCGI symptoms during the entire period of observation and about 23 percent of individuals had at least one episode. The overall incidence of HCGI was 0.66 episodes per person per year and the mean duration of an episode was 1.9 days. The yearly incidence of HCGI symptoms was higher in Period 1 (Table 4A) than in Period 2 (Table 4B). Age was a strong determinant of incidence of HCGI symptoms with the highest rates in the under 5 age group.

Table 5 reports the incidence rates in the two groups adjusted to the covariate distribution of the tap water group. Three units of observation were analyzed: the family as a whole, the informant, and the youngest child within the family. Again, the pattern of difference between tap and filtered water groups was quite similar for the different units of observation and across the two periods. Using the entire family data, the preventable fraction was 35 percent in the Period 1 and 32.8 percent in the Period 2. Combining the two periods, the adjusted incidence rates were 0.76 in the tap water group and 0.50 in the filtered water group ($p < 0.01$).

The HCGI episode is a synthetic combination of a number of GI-related symptoms. Similar analyses were done for each of the symptoms included in the diary: the findings were very similar to what was observed for the synthetic HCGI variable.

Dose-Response Relationship

To determine whether increased tap water consumption in the home was associated with increased risk of morbidity, we restricted attention to the tap water group. Poisson regression analyses were carried out with the number of episodes in the entire second period as the dependent variable and the estimated number of glasses of water consumed per week as an independent variable. Table 6 shows that for both informants and youngest chil-

[a] Most of these were due to a youngest child leaving home or reaching 18 years of age.

TABLE 3—Mean Number of Glasses of Water Consumed Weekly by Type of Water and by Group[a]

Type of Water Consumed	Group Filtered Water	 Tap Water
At home		
Filtered water	37.4	0.0
Tap water	1.9	37.8
Away from home		
Filtered water	0.3	0.0
Tap water	7.7	8.7

[a] Based on a separate survey of the study population. Responses were obtained from 957 subjects in the filtered water group and 891 in the tap water group.

dren, there was an increasing risk with increasing consumption. Among the tap water group there was no relationship between the quantity of water consumed outside the home and morbidity. Among the filtered water group there was no relationship between the quantity of water consumed inside or outside the home and morbidity (results not shown).

Nature of the Excess

Analyses were also carried out to determine whether the higher incidence in the tap water group was due to more people experiencing symptoms or whether it was due to the same core of people experiencing more episodes. These analyses were restricted to those families for whom complete data were available for the entire study. As shown in Table 7, there was a slight difference between the two groups in the percentage of subjects with episodes, but the number of episodes per person affected was considerably higher in the tap water group than in the filtered water group. This implies that the main effect of tap water consumption was to increase the number of episodes among susceptibles.

Discussion

This randomized trial was carried out to determine whether drinking water conforming to currently accepted microbiological standards was the source of any excess of GI disease when compared with a group drinking the same water after a molecular filtration to remove contaminants. The study was carried out in a relatively homogeneous middle class suburban neighborhood, and the overall observed incidence of gastrointestinal symptoms was similar to incidence rates reported in other North American populations.[19–21] The difference between the periods is within range for this type of symptoms. There was, however, a clear and significant excess of HCGI symptoms among the tap water drinkers as compared with filtered water drinkers. This finding was bolstered by the relative consistency of the effect across different age, sex, subregion, and informant/proxy categories, and the observation that among tap water drinkers there appears to be an increasing risk with increasing consumption.

Before proceeding to speculate as to the reasons and impact of these findings, it is important to consider possible sources of bias, the main one being reporting bias. Although the intervention was randomized, study subjects were not blinded. The possibility of having a sham filter installed in homes of tap water subjects was considered, but it was not technically and financially feasible. Subjects with a sham filter would have perceived the inefficacy of their filter and would have recognized the characteristic chlorine odor of tap water.

It is conceivable that subjects participating in the tap water group but aware of the study objectives exaggerated their morbidity relative to the filtered water group. Similarly, subjects in the filtered water group, if they had faith in the quality of their water may have underestimated their morbidity. However, we doubt whether such biases had any significant effect. Symptoms such as vomiting and liquid diarrhea are not subjective and open to interpretation. If such biases were operating, it is likely that they would be most pronounced at the outset and diminish with time as the novelty of the health diary wore off. However, over the 15-month study period, the relative excess of GI disease was fairly constant, arguing against any such bias. Furthermore, the observation of a dose-response relationship is less plausibly attributable to such biases. As a general check on the credibility of the quality of reporting, it is of interest that the estimated incidence rate is similar to reports from other North American centers and the relative consistency of the effect across the different categories.[19–21]

Outside the home, study subjects from both groups consumed water from all kinds of sources. Thus there was some misclassification in labeling one group as tap water consumers and the other as filtered water consumers. Moreover, this would tend to attenuate the effect of any true difference due to domestic water source and thus reinforces the importance of the difference observed. Similarly, the finding of an apparent dose-response relationship in the tap water group is particularly impressive given the crudeness of the measure of dose which was based on a one-point-in-time survey. The treated water leaving the filtration point was free of bacterial pathogens and indicator bacteria as well as of cultivable human enteric viruses.

Public Health Impact

In the past decade, there has been growing concern about the safety of public water supplies. Much of this concern has focused on presumed noninfectious outcomes such as cancer and birth defects and, in this context, there is some fear that chlorination byproducts may be harmful.[10,22] Heretofore, it was assumed that current water quality standards were sufficient to protect the public against the risk of GI disease; the apparent lack of outbreaks seemed to support this view. Our results suggest that there is a non-trivial endemic level of unreported GI diseases due to the consumption of tap water; 35 percent of gastrointestinal illness was estimated to be attributable to the consumption of drinking water meeting current water quality standards.[5]

The main impact of tap water consumption seemed to be in increasing the numbers of episodes of susceptibles rather than in increasing the numbers of people with episodes. The severity of these illnesses was low and resulted in few demands on the health care system. The community studied is typical of many North American communities in terms of its water source being contaminated by sewage discharges, its modern water treatment facilities, its treatment procedures which are widely used, and its sociodemographic characteristics. Our results raise questions about the adequacy of current standards of drinking water quality, including source water quality, treatment procedures, and bacteriological quality of the water in the distribution system as well as in-house plumbing. ☐

Acknowledgments

The quality of the data gathered during this study was made possible only through the commitment of Denise Bourbonnais to whom the authors express their sincere appreciation. The authors are grateful to Jean Pellerin who set up the data management system and to Marie Désy who helped carry out the statistical analysis. The authors also acknowledge the skillful technical work of Nicole Filion, Louise Courtemanche, and Chantal Germain who were responsible for the virological and microbiological analyses. The authors are indebted to Dr. Al Dufour (USEPA, Cincinnati) and Dr. Richard Tobin (Environmental Health, Health and Welfare Canada, Ottawa) for their continuous support in the preparation and follow-up of this study. The help of the Ministry of the Environment of Quebec, through the use of laboratory facilities and expertise in the Montreal Laboratory, was also extremely important in the success of this study.

Risk Assessment and Control of Waterborne Giardiasis

Joan B. Rose, PhD, Charles N. Haas, PhD, and Stig Regli

ABSTRACT

Background: Waterborne giardiasis has been increasing in the United States with 95 outbreaks reported over the last 25 years. The Safe Drinking Water Act has mandated control of this pathogen.

Methods: A risk assessment model was developed to estimate risk of infection after exposure to treated waters containing varying levels of *Giardia* cysts. The model was defined by a dose-response curve developed from human feeding studies for *Giardia* and assumed 2L of water consumption per day. Data on concentrations and distribution of the organism in source waters were used to assess exposure after varying reductions achieved through treatment.

Results: In surveys reporting prevalence and levels of *Giardia* cyst contamination, average levels of cysts in surface waters ranged from 0.33 to 104/100L; from pristine watersheds (protected from all human activity) 0.6 to 5/100L. Yearly risks were 4.8×10^{-3} for systems using polluted waters and 1.3×10^{-4} for pristine waters with a 10^{-3} treatment reduction.

Conclusion: Public Health officials will need to work with the water industry to ensure a risk of less than 1/10,000 for source waters with 0.7 to 70 cysts per 100 liters through treatment achieving reduction of 10^{-3} to 10^{-5}, respectively, of *Giardia* cysts. (*Am J Public Health.* 1991;81:709–713)

Introduction

Giardia is the most frequently isolated enteric protozoan from populations worldwide and the most common pathogenic parasite in the United States.[1] Waterborne giardiasis has been increasing in the United States with 95 outbreaks reported over the last 25 years,[2] and *Giardia* is the most common identifiable etiological agent of all waterborne outbreaks. Bennet *et al.*[3] have also estimated that 60 percent of all *Giardia* infections are acquired through contaminated water.

Giardia cysts may be found in water as a result of the deposition of fecal material from both man and animals. Surveys of *Giardia* cyst levels in various waters indicate that 26–43 percent of the surface waters were contaminated with *Giardia* cysts ranging in concentrations from 0.3 to 100 cysts per 100L.[5-10] Sykora[9] has reported an average of 10^4 cysts/100L in raw sewage with an approximate reduction of 10^{-2} after treatment (152 cysts/100 L).

The Surface Water Treatment Rule has been promulgated to address the amendments to the Safe Drinking Water Act for controlling *Giardia* in treated drinking water.[4] This rule mandates that all surface waters be treated to achieve at least a reduction of 10^{-3} (99.9 percent removal) of *Giardia* cysts. Disinfection is required for all systems and filtration is required unless the system meets site specific criteria and has a protected watershed. The US Environmental Protection Agency (EPA) has also recommended that a treatment be provided to ensure that populations are not subject to risk of infection of greater than 1:10,000 (10^{-4}) for a yearly exposure, and that this is an acceptable level of safety for potable waters.

As the new regulations and rules come into effect, health departments will be called upon to ensure that the public is adequately protected against waterborne disease. Risk assessment is a tool by which health officials can communicate with the water industry by interpreting water quality surveys and assisting in defining the adequacy of treatment adhering to EPA's recommendations of potable water quality and acceptable public health risks. This will become particularly important as states implement the Surface Water Treatment Rule, evaluate new technologies, and determine what water management practices will impact public health.

This paper presents a risk assessment model that was used to estimate risk of infection due to waterborne exposure to *Giardia*. Dose-response curves were developed based on human infectivity studies, and data on the occurrence of *Giardia* cyst contamination in waters throughout the US were used to define the water treatment needed to reduce the risk of waterborne giardiasis.

Methods

To predict a potential public impact when the risk is small, models are used to estimate the risk after exposure. Haas reviewed three probability models for their ability to describe experimental dose-response data for humans after exposure to

This paper, submitted to the Journal April 19, 1990, was revised and accepted for publication December 10, 1990.

various enteric microorganisms.[11] Using the same approach, the simple exponential and beta distributed effectiveness models were evaluated for prediction of *Giardia* infectivity using experimental data developed by Rendtorff[12,13] in human feeding studies.

In Rendtorff's experiments, *Giardia* cyst doses ranging from 1 to 10^6 were fed to volunteers, and a positive response was measured by cyst excretion in the feces (Appendix). Laboratory dose-response studies generally appear to be conducted under conditions where the distribution of microorganisms in the administered dose may be regarded as Poisson. Under these conditions, if one microorganism is sufficient to cause an infection, and if host-microorganism interactions are constant, then the probability of an infection (P_i) resulting from ingestion of a single volume of liquid containing an average number of organisms (N) may be defined by a simple exponential equation.

$$P_i = 1 - \exp(-rN)$$

In this equation, r is the fraction of microorganisms that are ingested which survive to initiate infections ("host-microorganism interaction probability") (Appendix). In this particular case, the exponential model was statistically consistent with the Rendtorff data and r was calculated to equal −0.01982.

The 95 percent confidence limits to the parameter r in the exponential model were computed using a likelihood ratio technique. The resulting interval estimate for r is 0.009798–0.03582. This range was used in the preparation of Figure 1.

Exposure Estimates

Surface waters were classified into two categories: polluted waters contaminated by sewage and agricultural discharges; and pristine waters originating from protected watersheds without point source pollution or input from human activities. *Giardia* cyst levels were examined for the peak level of contamination from a single sample, average concentrations for each site, and average cyst levels for each water classification. Geometric means were calculated from the average concentrations from each site.[5–10] *Giardia* cyst levels were calculated as cysts/100 L as large volumes of water are routinely sampled for determining levels of contamination.

Using the exponential model, the potential risk of infection was determined with varying levels of *Giardia* cysts in drinking water. The model assumed the consumption of two liters of water per day, and exposure N in the formula was defined by numbers of cysts per liter times two liters. Levels of *Giardia* cysts found in polluted and pristine source waters and assumed levels of 10^{-3}, 10^{-4}, and 10^{-5} removal by treatment were used to estimate exposure in the model. Maximum daily risk was estimated using the peak level of contamination and yearly risk was determined using the geometric mean concentration of *Giardia* cysts for 365 days of exposure. Probability of infection was determined assuming a Poisson distribution of microorganisms in the drinking water,[11] i.e.,

> risk of contracting one or more infections = $1-(1-\Pr(N))^x$ where x = the number of days exposed and Pr(N) = the daily risk using the geometric average for N.

Data from five waterborne outbreaks of giardiasis were also evaluated for the *Giardia* cyst level of contamination detected in the drinking water and the attack rates in the exposed population.[14] This information was compared to the estimated infection rates developed by the exponential model after varying days of exposure.

Results

To ensure less than a daily risk of 10^{-4}, systems using source waters containing 250, 2,500 and 25,000 cysts per 100L would need to reduce the level of *Giardia* cysts by 10^{-3}, 10^{-4} and 10^{-5}, respectively, through drinking water treatment (Table 1). Examples of yearly risks for exposure to varying levels of *Giardia* cysts in drinking water are summarized in Table 2. To ensure less than a yearly risk of 10^{-4}, systems using source waters containing a geometric concentration of 0.7, 7.0 and 70 cysts per 100L would require a reduction of 10^{-3}, 10^{-4} and 10^{-5}, respectively, by treatment.

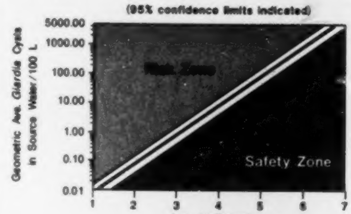

FIGURE 1—Log 10 Treatment Reductions for *Giardia* Cysts in Source Waters Yielding 10^{-4} Annual Risk (95% confidence limits indicated)

In surveys reporting prevalence and levels of *Giardia* cyst contamination in surface waters, average levels of cysts ranged from 0.33 to 104/100L. Eight of the areas where samples were collected from received treated sewage or agricultural discharges, however, the level of pollution was not documented.[5–10] In water samples originating from pristine watersheds (protected from all human activity) *Giardia* cyst levels averaged 0.6 to 5/100L. The percentage of positive samples did not vary dramatically from polluted to pristine waters (43 percent and 35 percent, respectively). Peak contamination in a single sample was 5.5 times higher from polluted waters than from pristine waters. However, geometric averages of cysts were 50 times higher for samples collected from polluted waters versus those collected from pristine waters.

The majority of data for the pristine waters was developed from a study by

[a] geometric average
[b] Risk = 1−(1−Pr(N))^{365}

Ongerth, *et al.*[6] The Tolt, Green and Cedar watersheds in the State of Washington were extensively sampled with 222 samples collected. The averages reported in the publication included a 22 percent recovery adjustment for method efficiencies. The data from the Ongerth study[6] used in this paper did not include such adjustments since the data used from other studies[5,7–10] did not take into account adjustments for recovery efficiencies.

Daily and yearly risks were developed for the peak cyst level and the geometric average, respectively, for the two water categories (Polluted and Pristine). The data are shown in Table 3. Yearly risks ranged from 4.8×10^{-3} for systems using polluted waters with a 10^{-3} treatment reduction to 1.3×10^{-6} for pristine waters with a 10^{-5} treatment reduction. Between 10^{-4} and 10^{-5} reduction with treatment would be required for polluted waters to achieve a similar risk as pristine waters treated for a 10^{-3} removal of *Giardia* cysts. For daily risks for waters containing peak levels of *Giardia* cysts, the differences were not as dramatic between systems using polluted versus pristine source waters. The peak daily risk was approximately five times greater in systems using polluted versus pristine waters receiving similar treatment for removal of cysts.

Water samples were collected and *Giardia* cyst levels were determined during the investigation of five waterborne outbreaks of giardiasis. Attack rates varied from a low of 0.5 percent in the Houtzdale and Pittston outbreaks to a high of 16 percent in the Ft. Plain outbreak. The level of cyst contamination ranged from 0.6 to 21 cysts/100L. Generally the lower levels of contamination were associated with lower levels of infection in the population. The data are shown in Table 4.

All five outbreaks were associated with unfiltered chlorinated surface waters. Three factors primarily influenced the attack rate for infection: first, the level of contamination; second, the level of cyst viability and inactivation through chlorination; and third, the length of exposure to the population whose prior exposure to *Giardia* (and potential immunity) was unknown. Much of this detail is not known. The exponential risk model was applied to the known cyst levels from the outbreak and infection rates were estimated for varying days of exposure. It is unlikely that there was a single day of exposure or that the exposure was equal to the duration of the outbreaks. If one uses intermediate times of exposure, five to 10 days, the infection rates developed by the model ranged from 0.1 to 7.7 percent.

Discussion

Many regulatory and public health agencies have accepted risk assessment models to evaluate the importance of chemical pollutants in water. How well these models reflect reality depends on the accuracy of the model for characterizing the independent variables, assumptions, and the data used to develop the dose-response curves and exposure.

The most essential component to the risk model described in this paper is the dose-response curve. *Giardia* species/strains are known to have a low infectious dose. Rendtorff and Holt demonstrated in 1954 that ingestion of as few as 10 cysts was capable of initiating infection in two volunteers. It must be kept in mind that infection was measured by cyst excretion and illness was not determined. Asymptomatic *Giardia* infections may range between 39 percent and 76 percent for children less than five years of age and adults, respectively.[15,16] Symptomatic infections, however, have been reported at a rate of 50 percent to 67 percent and as high as 91 percent.[17] Chronic giardiasis may also develop in as many as 58 percent of the population infected.[18] Thus the illness to infection ratio is highly variable. We addressed only infection in this analysis of risk.

Another important issue regarding the dose response curve based on the Rendtorff data is uncertainty about infectivity due to strain variation and the immune response to infection by different populations. The Rendtorff data are derived from one *Giardia lamblia* strain and one relatively small sample population. The confidence interval around the probability of infection does not take these uncertainties into account when using the model as a predictive tool.

Assuming the dose response relationship derived from the Rendtorff data is representative, we may be overestimating

TABLE 4—*Giardia* Cyst Contamination of Drinking Waters during Waterborne Outbreaks of Giardiasis and the Relationship to an Exponential Risk Model

[b] Estimated from the exponential risk model.

risks based on the assumption that all cysts are viable and all cysts in water are species which infect humans. In addition, the 2L of tap water consumption may represent overestimation of exposure, depending on individuals consumption of other beverages. However, the underestimation of risk may be of greater concern due to underestimation of exposure by the inefficiencies of the methods for detection of *Giardia* cysts in water.

In spite of its limitations, the model can be used to examine waterborne outbreak data and disease surveillance data associated with various exposure routes. Epidemiological data, may be even more insensitive and inaccurate. Attack rates for waterborne outbreaks, defined by the number of illnesses in the exposed population, are developed using a variety of methods; they do not take into account unreported cases or asymptomatic infections, and may include individuals who were not exposed. Estimation of infection based on attack rates is probably understated.

Levels of cysts ranging from 0.6 to 21/100L detected in waters were associated with outbreaks of disease. *Giardia* cyst levels found in drinking waters averaged 0.19/100L during non-outbreak conditions and were rarely above 1/100L.[19] Based on the data in Table 4, it appears the model may be useful in estimating probability of infection. The greatest limitation of the model may be the underestimation of infection and disease through the use of cyst concentrations in water without taking into account method efficiencies, peak contamination levels, and duration of exposure.

By applying information on *Giardia* cyst levels to Figure 1, public health agencies, regulatory agencies, and water utilities can evaluate the adequacy of current treatment of a drinking water supply, the need for more effective treatment, or the type of treatment needed in developing new water supplies.

Public health workers must not only have an understanding of waterborne disease. The implications of new regulations, watershed protection, and water treatment on indigenous potential waterborne infections in the population must also be understood. Standard methods are available to assess *Giardia* cyst contamination in water. Health agencies can utilize such data in a risk assessment, cost-benefit approach to establish rational policies for public health protection. ☐

APPENDIX

For the purpose of modeling, it was assumed that the cysts have a random distribution in water and that a Poisson distribution would govern the probability of any given exposure.[11] The risk of infection was defined as a function of the exposure (N organisms) and the interaction of the host and pathogen. The parameters characterizing this interaction (r) were determined using the human infectivity data set. The data set for the experimental infection and development of the model areshown in Table A-1. The single-hit exponential equation for the probability of infections is shown in Table A-2. The constant characterizing the host-cyst interaction with the best fit values to the data set is also presented. An average r value (that fraction of microorganisms that are ingested which survive to initiate infection) for the exponential model was computed by determining the value of r at each dose. The chi square goodness of fit test was used to evaluate the appropriateness of the model for the data set.The single hit exponential model was used toevaluate the risk of waterborne giardiasis. Low level contamination of drinking water with *Giardia* (0.5 cysts/100L)would result in a potential infection rate of 0.02 percent in the exposed population using the exponential model while at high levels of contamination, (100 cysts/100L) a 3.9 percent infection rate was determined (Table A-3).

Lyme Disease: A Proposed Ecological Index to Assess Areas of Risk in the Northeastern United States

ABSTRACT

Background: Recent public awareness has resulted in a demand for information about ways to reduce the risk of acquiring Lyme disease.

Methods: Twenty-two school properties and recreational areas within a Lyme disease endemic area of central Monmouth County, New Jersey were evaluated for risk of transmission using an ecological index on the suitability, amount, and access to *Ixodes dammini* habitat by target human populations and the abundance of infected adult ticks.

Results: The characterization of tick habitat accurately predicted the elimination of 11 sites from concern. Of the remaining 11 sites, six were classified high risk and five as moderate risk. On-site tick surveys identified infected *I. dammini* adults at only four sites (three risk; one moderate risk).

Conclusions: These results indicate that the use of selected ecological parameters provides a cost-effective method to rapidly identify areas at risk for Lyme disease transmission. (*Am J Public Health.* 1991;81:714–718)

Terry L. Schulze, PhD, R. Chadwick Taylor, MBA, George C. Taylor, MPH, and Edward M. Bosler, PhD

Introduction

The extensive media attention recently afforded to Lyme disease has resulted in a dramatic increase in public awareness and demand for information regarding this tick-borne, spirochete-induced illness. The public is concerned about ways to reduce the risk of acquiring Lyme disease, including the relative safety of discrete geographical areas such as schools, recreational areas, and residential communities.

Early ecological studies in New Jersey identified areas of potential risk at the regional level through deer surveys[1] and serosurveys of canines.[2] As Lyme disease became more prevalent, areas at risk were determined by plotting case reports.[3] While local health officials could identify general areas at risk by randomly conducting tick surveys or retrospectively plotting case reports, a cost-effective method to prospectively identify specific geographical areas at risk for Lyme disease was unavailable. We propose here an index for use by public health and allied agencies which systematically assesses specific geographical areas for potential and actual risk of Lyme disease transmission through evaluation of key ecological parameters.

Methods

Study Sites

In response to increased public inquiries, the Freehold Township Health Department petitioned the New Jersey State Department of Health for assistance in evaluating the relative risk of Lyme disease transmission at all eight public school properties and 14 recreational areas within its jurisdiction. The public school properties ranged in size from 4.83 to 69.59 acres ($\bar{x}$ = 19.80 acres). The recreational areas ranged in size from 0.5 to 200 acres ($\bar{x}$ = 40.5 acres).

Identification of Tick Habitat

The northern deer tick, *Ixodes dammini* Spielman, Clifford, Piesman and Corwin is most prevalent in wooded areas, associated ecotones, and old fields in secondary woody succession.[4] Extensive surveys of potential tick habitats common to the Inner and Outer Coastal Plains of New Jersey where the majority of Lyme disease cases are reported[3] confirmed these associations (unpublished data). In upland areas of the coastal plain physiographic regions of New Jersey and other northeastern states, habitats generally yielding the highest populations of *I. dammini* are comprised of mixed hardwood, mixed hardwood/pine, and pine forests with a dense shrub layer dominated by highbush blueberry, *Vaccinium corymbosum* L.; lowbush blueberry, *Vaccinium angustifolium* Ait.; and huckleberries, *Gaylussacia* spp. with some mountain laurel, *Kalmia latifolia* L.; bayberry, *Myrica pensylvanica* Loisel; and catbrier or greenbrier, *Smilax* spp.[5]

TABLE 1—Summary of *I. dammini* Abundance and Infection Rates from Recreational Areas Yielding Ticks in Freehold Township, New Jersey

Surveyed Area	Number of Adult Ticks (60-Minute Survey)	Rate of Infection by *B. burgdorferi* (%)
A	48	41.7
B	88	57.1
C	28	50.0
D	24	33.3
NWS Earle	74–180	41.9

Tick Surveys

Tick surveillance would normally be scheduled only for those sites identified as having high or moderate risk of potential transmission based on the evaluation of habitat. To test the efficacy of the proposed index, all 22 sites were surveyed for the presence of ticks. Tick populations were evaluated during the period of peak adult activity in the fall by walking throughout suitable tick habitat at each of the subject sites for a 60-minute period.[4,6] At smaller sites, the survey time was reduced and the number of ticks collected was extrapolated to the 60-minute survey period for ease in comparison. This recognized survey technique provides an accurate representation of the expected number of adult ticks to be encountered by humans.[7] When no suitable habitat was present, the site was then randomly walked. Ticks adhering to investigators' light-colored, cotton coveralls were removed and subsequently evaluated for the presence of spirochetes using dark-field microscopy.[8] Based on previous studies in Monmouth County, the spirochetes identified in this study were assumed to be *Borrelia burgdorferi.*[9]

Ecological Index

The proposed ecological index is designed to use information on the type of plant communities and abundance of infected adult *I. dammini* to rapidly predict the risk of Lyme disease transmission at discrete geographical sites. Although plant communities may be assessed throughout the year, the seasonality of adult tick activity would naturally restrict the use of the proposed index in New Jersey to early spring and fall.[10] To alleviate this problem, the index was divided into two phases. Phase I permits the characterization of a site with respect to potential risk of transmission in the absence of tick activity by evaluating the suitability, amount, and accessibility of *I. dammini* habitat. Point values ranging from a minimum of 1 to a maximum of 5 are assigned to each of the three ecological parameters and totaled. The resulting score is used to select the appropriate response action for each site and determine the need to proceed to Phase II of the proposed index.

Rather than sole reliance on habitat to predict the risk of transmission at a particular site, Phase II of the proposed index is designed to utilize, in conjunction with the information on habitat, data on the presence and size of the deer tick population, and rate of *B. burgdorferi* infection. Point values of 1 to 5 are assigned to each of the five ecological parameters and totaled to achieve a final score for each site. This scoring procedure is used to categorize actual risk and establish priorities for intervention strategies.

Detailed descriptions of the ecological parameters, scoring procedures, and response actions for both phases of the proposed ecological index along with the survey form are provided in the Appendix in an instructional format.

Survey Procedure

The assessment of potential risk of transmission for each of the subject sites was performed on June 22, 1989 and July 19, 1989. To determine actual risk of transmission, the subject sites were surveyed for *I. dammini* between October 27, 1989 and November 8, 1989. These dates were well within the period of peak activity for *I. dammini* adults in New Jersey.[10] Surveys were performed only on fair days between 1000–1400 hours when peak diurnal activity was expected. Ticks collected during walking surveys were retained for subsequent analysis. Data on tick abundance and infection rate were recorded on the original survey form for each site. The sites were then ranked with respect to risk of transmission and need for intervention. To document that temporal and meteorological conditions were conducive to tick questing, a site at nearby Naval Weapons Station Earle (NWS Earle), Colts Neck, New Jersey exhibiting similar habitat and known to have consistently high populations of infected *I. dammini*[9] was also surveyed for ticks on each of the study dates.

Results

Potential Risk of Transmission

Of the eight public school properties, only one demonstrated high risk of transmission. Moderate risk of transmission was assigned to one school, while the remaining six schools received a low risk rating.

Regarding the recreational areas, five of 14 were considered to have high risk of transmission ratings, while four sites were assigned moderate risk of transmission ratings. The remaining five recreational areas received low risk of transmission ratings.

Actual Risk of Transmission

None of the eight school properties surveyed yielded *I. dammini* adults. On the survey days, the site at NWS Earle produced 88 and 114 ticks per 60-minute survey, confirming tick activity on the survey dates. Of the eight schools, one was classified as limited risk, three as no present risk, and four as no risk likely.

Ticks were collected from only four recreational areas. In 60-minute surveys, the four sites yielded between 24 and 88 adult ticks. At the NWS Earle site, 74, 88, and 180 ticks were collected in equivalent 60-minute surveys, again confirming tick activity. Minimum field infection rates at the four recreational sites ranged between 33.3 percent and 57.1 percent. During the survey period, 41.9 percent of adult ticks collected from NWS Earle were infected with spirochetes. The tick collection and infection rate data for sites yielding ticks are summarized in Table. 1. As a result of tick surveys, two of the 14 recreational sites were classified as definite risk, three as potential risk, one as limited risk, three as no present risk, and the remaining five as no risk likely.

Discussion

The proposed ecological index was designed for use in upland areas of the coastal plain physiographic regions of the northeastern United States where the majority of Lyme disease cases occur.[11] In this investigation, the proposed index provided a rapid, systematic, and cost-effective method of eliminating from public health concern high use public property by assessing the ability of existing plant communities to serve as habitat for *I. dammini.* Once significant potential risk was determined by surveys of vegetation, the actual risk of transmission and appropriate response action were determined based on the abundance of infected adult deer ticks. Where the response action may include chemical control, the proposed index will assist the user in identifying areas requiring treatment, thereby reducing unnecessary acaricide applications.

Although tested on only 22 sites comprising 725 acres within a hyperendemic area of New Jersey, we believe that, with minor modifications, the proposed index can be used in other ecosystems and for other tick vectors. For example, the "suitability of habitat" parameter can be modified to reflect differences in vegetation utilization by deer ticks in the ecosystem under investigation. Although we found the collection of adult ticks to be the most cost-effective method in characterizing the deer tick population, other survey techniques may be substituted to evaluate subadult *I. dammini* or other tick vectors. In such cases, criteria of the "tick abundance" and "tick infection rate" parameters will require modification. The proposed ecological index is designed to be a flexible survey instrument that provides public health officials and others with a means to rapidly assess the potential and actual risk of Lyme disease transmission at various sites within their jurisdictions. ☐

Instructions for Use of Lyme Disease Survey Form

Index Parameters

Phase I of the ecological index prospectively assesses discrete geographical sites for the potential risk of Lyme disease transmission by evaluating three ecological parameters. In the absence of tick data, point values are assigned to reflect the degree to which each parameter enhances the likelihood of transmission. In addition to these three parameters, Phase II employs tick abundance and tick infection rate to categorize these sites for the actual risk of Lyme disease transmission. Point values were similarly assigned to these parameters to complete the assessment.

Parameter Number	Parameter Description	Point Value	
		High	Low
1	Suitability of Habitat	5	1
2	Amount of Habitat	5	1
3	Accessibility of Habitat	5	1
4	Tick Abundance	5	1
5	Tick Infection Rate	5	1

Description of Parameter

1. Suitability of Habitat

This parameter addresses the suitability of the habitat (plant community) at the subject site for supporting populations of *Ixodes dammini* ticks.

Point Value	Habitat Description
5	= mixed hardwoods or mixed hardwoods/pine forest with substantial (>75% coverage) shrub layer dominated by highbush blueberries, lowbush blueberries, and huckleberries with some laurels, bayberries, catbrier, saplings/seedlings of the aforementioned tree species, and associated ecotones (Type 1 habitat).
4	= same as above except with a modest (25%–50% coverage) shrub layer (Type 2 habitat).
3	= same as above except with a sparse (<25% coverage) shrub layer or fields in secondary woody succession (Type 3 habitat).
2	= meadows, overgrown fields, or forested wetlands.
1	= agricultural fields, athletic fields, lawns, etc.

2. Amount of Habitat

This parameter represents the amount of habitat (Types 1, 2, and/or 3) at the subject site able to support populations of *Ixodes dammini* ticks.

Point Value	Amount of Suitable Tick Habitat
5	= 80% to 100% of subject site
4	= 60% to 79% of subject site
3	= 40% to 59% of subject site
2	= 20% to 39% of subject site
1	= 0% to 19% of subject site

3. Accessibility of Habitat

This parameter provides an estimate of how accessible the suitable tick habitat at the subject site is to the human population at risk.

Point Value	Description of Accessibility
5	= suitable tick habitat is easily accessed or people are encouraged to access the subject site (picnic areas, hiking or exercise trails, campsites, place of residence, playgrounds, school yards, etc).
4	= suitable tick habitat adjacent to subject site and readily accessible.
3	= suitable tick habitat present, but access discouraged because of natural or man-made barriers (catbrier, multiflora rose, or other impenetrable vegetation; water; fences; etc.); the area is totally undeveloped; or the amount of suitable habitat is limited.
2	= access to suitable tick habitat restricted (military facilities, private clubs, etc).
1	= no access or no suitable tick habitat present.

(continued)

APPENDIX continued

4. Tick Abundance

This parameter addresses the relative number of *I. dammini* adults in habitats within the subject site. The number of *I. dammini* adults collected during 60-minute walking surveys (or extrapolated equivalent) will be used for this phase of the ecological index.

Point Value	Tick Abundance
5	= >30 *I. dammini* adults per survey
4	= 11–29 *I. dammini* adults per survey
3	= 6–10 *I. dammini* adults per survey
2	= 1–5 *I. dammini* adults per survey
1	= 0 *I. dammini* adults per survey

5. Tick Infection Rate

This parameter takes into account the percentage of *I. dammini* adults collected at the subject site that are infected with *Borrelia burgdorferi.*

Point Value	Tick Infection Rate
5	= >40% of *I. dammini* adults infected
4	= 30% to 39% of *I. dammini* adults infected
3	= 20% to 29% of *I. dammini* adults infected
2	= 10% to 19% of *I. dammini* adults infected
1	= 0% to 9% of *I. dammini* adults infected

Scoring and Response Actions—Potential Risk of Transmission

After point values are assigned to each of the three ecological parameters, the point values are totaled to achieve a final score for the subject site. The final score is then compared to the three point ranges presented below to determine the appropriate response action for the subject site.

The response action designations are to be used by the investigator to assign priorities to sites within his/her jurisdiction with respect to potential risk of Lyme disease transmission in the absence of any data on tick abundance and rates of infection by *B. burgdorferi.* This phase of the ecological index may also serve as a guide/provide justification for use of limited resources.

Scoring Range	Description of Risk	Response Action
11–15	High Risk	Place under routine tick surveillance and establish rates of infection.
6–10	Moderate [illegible]	Consider periodic tick surveillance and establishment of infection rates.
<6	Low Risk	No action necessary at this time or any time in the future.

Scoring and Response Actions—Actual Risk of Transmission

Point values relating to the habitat parameters (Parameters 1–3) are totaled first. This figure is recorded and separated from the point value for Tick Abundance (Parameter 4) by a slash (/). The point value for Tick Infection Rate (Parameter 5) is similarly separated from the remainder of the index by a slash. As such, a site receiving the maximum rating for each parameter would be recorded as 15/5/5. By recording the point values in this fashion, the ecological index becomes more descriptive, allowing the investigator to rapidly determine the relative importance of habitat, tick abundance, and tick infection rate in the assessment of the subject site.

After the point values for the five ecological parameters are recorded as above, the point values are totaled to achieve a final score for the subject site. The final score is then compared to the 5 point ranges presented below to determine the appropriate response action for the subject site.

Scoring Range	Description of Risk	Response Action
21–25	Definite Risk	Take immediate action (post area, devise control strategy).
16–20	Potential Risk	Consider action as above, but with a lower priority; place under routine tick surveillance.
11–15	Limited Risk	Perform periodic tick surveillance.
6–10	No Present Risk	Consider periodic tick surveillance; no action necessary.
<6	No Risk Likely	No action necessary at this time or at any time in the future.

Cancer Rates after the Three Mile Island Nuclear Accident and Proximity of Residence to the Plant

Maureen C. Hatch, PhD, Sylvan Wallenstein, PhD, Jan Beyea, PhD, Jeri W. Nieves, MS, and Mervyn Susser, MB, BCh

ABSTRACT

Background: In the light of a possible link between stress and cancer promotion or progression, and of previously reported distress in residents near the Three Mile Island (TMI) nuclear power plant, we attempted to evaluate the impact of the March 1979 accident on community cancer rates.

Methods: Proximity of residence to the plant, which related to distress in previous studies, was taken as a possible indicator of accident stress; the postaccident pattern in cancer rates was examined in 69 "study tracts" within a 10-mile radius of TMI, in relation to residential proximity.

Results: A modest association was found between postaccident cancer rates and proximity (OR = 1.4; 95% CI = 1.3, 1.6). After adjusting for a gradient in cancer risk prior to the accident, the odds ratio contrasting those closest to the plant with those living farther out was 1.2 (95% CI = 1.0, 1.4). A postaccident increase in cancer rates near the Three Mile Island plant was notable in 1982, persisted for another year, and then declined. Radiation emissions, as modeled mathematically, did not account for the observed increase.

Conclusion: Interpretation in terms of accident stress is limited by the lack of an individual measure of stress and by uncertainty about whether stress has a biological effect on cancer in humans. An alternative mechanism for the cancer increase near the plant is through changes in care-seeking and diagnostic practice arising from postaccident concern. (*Am J Public Health*. 1991;81:719–724)

Introduction

Shortly after the accident at the Three Mile Island (TMI) nuclear power plant on March 28, 1979, some area residents believed an increase in cancer had occurred, although a detectable excess had not been predicted. In light of the low estimates of radiation emitted, the President's Commission on the Accident at Three Mile Island concluded that the sole health consequence for the population living nearby was mental distress.[1] Because of growing interest in the effects of stress on cancer promotion and progression, we attempted an ecologic test of the relationship between cancer rates and accident stress. Natural disasters have been associated with subsequent cancer risk in previous reports,[2,3] one of which proposed that a similar study be mounted in the Three Mile Island area.[3]

At Three Mile Island, levels of distress among area residents arose immediately after the accident[4–7] and alcohol consumption rose in parallel.[8] While distress levels were elevated, they were generally in the normal range and seemed to abate within nine months, although attitudinal effects such as distrust of authorities and concerns about safety persisted.[4,5] During clean-up and krypton venting at the plant, and restart of the undamaged reactor in October 1985, turmoil at Three Mile Island was ongoing and stress and consequent distress continued or recurred. A year after the accident, a sample of community residents exhibited significantly higher levels of stress hormones and stress symptoms than residents near undamaged nuclear or coal-powered plants although, again, the levels observed were within normal limits[9]; a similar survey five years postaccident found evidence of chronic stress.[10] Periodic resurveys of other cohorts at TMI have also showed persistent distress[11] and even clinical levels of anxiety, depression and hostility, particularly in those living close to the plant.[6,12–14]

In recent years, increased attention has focused on the possibility that stress and other psychosocial factors may affect the carcinogenic process[15–21]—perhaps through the action of corticosteroids on immune function[20,21] or of stress hormones like prolactin on regulation of neoplastic cell growth.[15,19] Indirect mechanisms involving behavioral risk factors also need to be considered, as do possible interactions between stress and other risk factors. While epidemiologic studies have looked for links between psychological states, personality traits, stressful life events and the onset and development of cancer, thus far the evidence is less than conclusive.[22–38] Two recent positive reports are fairly rigorous. In one, survival time for patients with metastatic breast cancer was found to be significantly increased among those randomized to a psychosocial intervention which reduced depression, anxiety, and pain.[39] In the other, severely stressful life events proved to be strongly predictive of a first recurrence of

breast cancer in carefully matched patients with previously operable tumors.[40]

A biologic rationale connecting stress and cancer does exist Inconsistent results from research in humans may indicate the lack of a true association, or a lack of understanding about how the neuroendocrine and immune systems mediate between psychosocial factors and cancer. In the present report, we summarize an *a priori*, if crude, test of the impact of an objective stress situation on a community's cancer rates.

Methods

The methods of this record-based geographic study are described in detail elsewhere.[41] Briefly, cancers among residents living within 10 miles of the TMI plant in the period 1975–85 were ascertained by review of patient charts at all local and regional referral hospitals (incident cases) and from vital certificates (deaths). The study area was divided into 69 small "study tracts," built up from census blocks, with populations ranging from 500-9,500 (2,300 on average). Cancers were assigned based on residence at diagnosis or at death, and for each study tract, annual rates of cancer incidence and mortality were calculated for the 11 years of the study period.

Cancer Sites Studied

In terms of the accident as a stressful event, we prespecified certain cancers or groupings of cancers for analysis, although there was little literature to guide us. Four categories were selected:

- *leukemias*, chosen because of their responsiveness to glucocorticoids, one of the "stress" hormones[42];
- *lymphomas*, which also respond to glucocorticoids and, in addition, are associated with immunosuppressive states[43];
- *"hormonally dependent" cancers* (breast, endometrium, ovary, prostate and testis), selected because stress hormones can alter concentrations of other hormones that affect cancer cells[19];
- the grouping *"all cancers"*, because in theory stress can influence the biology of all tumors through changes to the immune system.

Proximity as a Surrogate Measure of Stress

In the absence of any direct measure of stress, we used a surrogate measure supported by findings from the earlier psychosocial research at TMI. The measure is based on residential proximity to the Three Mile Island facility. A postaccident evacuation advisory issued by the Governor had focused public attention sharply on the area within a five-mile radius, with evident effect. Not only were evacuation rates higher in the five-mile radius, but so were rates of demoralization as determined by the President's Commission on Behavioral Effects.[4] Another population survey, by the Pennsylvania Department of Health,[5] found that as proximity increased so did the reported levels of perceived threat, of feeling "upset by the accident," and of psychophysiological symptoms. A study of mothers with young children found that those living in a five-mile radius of the TMI plant were more likely to experience a clinical episode of depression or anxiety than mothers living farther away.[14]

To evaluate residential proximity in the study reported here, we assigned each study tract a value corresponding to the distance between its midpoint and the TMI facility. The study area was also divided into three contiguous concentric rings based on natural breakpoints in the distribution of distances.

Proximity as Distinct from Radiation Emissions

While we treat residential proximity as a surrogate for accident-related stress, others have used it to define exposure to radiation near nuclear installations. Factors like wind direction, terrain, and elevation modify the distribution of exposures, however, and in the Three Mile Island area the terrain northeast and northwest of the plant directed emissions away from residents. In estimating radiation exposures, we developed mathematical models that take such modifying influences into account. Overlap between residential proximity and exposure to radiation emissions modeled mathematically is adjusted for in the analysis. A detailed description of the radiation emissions models is given in a separate report.[41]

Statistical Analyses

Logistic regression based on maximum likelihood estimation[44] was used to examine the age-sex-specific probability of cancer in relation to proximity of residence to the plant. Odds ratios derived from the logistic regression estimates were calculated contrasting median distance in the inner and outer rings. Indicator variables were used to adjust for a maximum of 16 age-sex categories (0–14, 15–24,. . . 65–74, 75 +). No adjustment was made for race since the population is over 96 percent White. Using aggregate data for each of the 69 study tracts, we adjusted for urbanization (population per km^2) and social class (median income; percent high school graduates), treating these measures as continuous variables.

The analyses were performed for both the preaccident period (January 1975-March 1979) and the period immediately following the accident (April 1979-December 1985). Where indicated, we used an unconditional logistic regression procedure to control for underlying heterogeneity among study tracts prior to the accident. This analysis, which is a means of adjusting for baseline risk, incorporates a parameter for each study tract, an indicator variable for period (preaccident or postaccident) and a distance variable coded zero before the accident and according to its assigned value after the accident. A conditional analysis based on a Poisson model gave similar results and is not presented here.

For descriptive purposes, we calculated standardized incidence ratios (SIRs) and standardized mortality ratios (SMRs) for the three rings at distances from the TMI facility of 0–6 km, >6–12 km, and >12 km, using age-sex-specific rates for Whites in the national Surveillance Epidemiology End Results (SEER) program (1978–81, Puerto Rico excluded).[45] However, interpretations are based on the regression analyses, which do not use an external standard.

Results

The distribution of population density, income and education by distance from the TMI plant (Table 1) shows that nearby areas are more urban and of lower socioeconomic status; these factors, as well as age and sex, are controlled in the logistic regression models.

Stress in Proximity to the Plant

For all cancers as a group, there is a statistically significant relationship between incidence rates (Table 2) after the accident and residential proximity to the plant (OR = 1.4; 95% CI = 1.3, 1.6). The association is present in both males (OR = 1.4; 95% CI = 1.2, 1.6) and females (OR = 1.5; 95% CI = 1.3, 1.7). Among the specific cancer categories tested, lymphoma shows the strongest association (OR = 1.9; 95% CI = 1.2, 3.0). Leukemias and hormonal tumors show associations of about the same magnitude as for all cancers. In addition, two common tumors

(lung and colon) also show associations with proximity to TMI (OR = 1.7 for each). The observed increase in "all cancers" thus seems to be due to increases in several cancer types.

For the "all cancer" grouping, rates in the area close to the plant are higher before the accident as well as afterwards. We corrected for the preaccident pattern by means of the procedure described above; the odds ratio adjusted for risk at baseline was reduced from 1.4 to 1.2 (95% confidence limits = 1.0, 1.4).

In Figure 1 we show incidence rates for all cancers for each year of the study period by proximity to the plant (three distance rings). By 1982, rates in the area closest to TMI were clearly elevated. The numbers of cases among residents of the inner ring rose from a yearly average of less than 50 to a high of 78 (a value that lies outside the 99% CI around 50 (33.7, 71.3), assuming the number of cases to be a Poisson variable). By 1984, the cancer rate had fallen to preaccident levels and by 1985 was lower than the rates in the more distant rings.

Mortality data (Table 3) suggest no general increase in cancer deaths with proximity to the plant in the postaccident period compared to the preaccident period. Neither do mortality rates for all cancers by year show any evidence of a change (data not presented).

Detection Bias

To test for detection bias arising from postaccident concern about cancer risk, we compared the relationship between stage at diagnosis and residential proximity to the plant in the periods before and after the event. Cancers of the breast, lung, colon, and prostate were selected since screening is common for these sites (see Table 4). With breast cancer, a shift in the postaccident period to an earlier stage at diagnosis is seen only among residents of the middle ring. For prostate cancer, residents of the inner ring actually show a decrease in the proportion of tumors diagnosed at an early stage after the accident compared to before. Lung and colon cancer show the reverse: after the accident, a higher proportion of tumors was diagnosed early among those living close to the plant.

Discussion

In an admittedly crude test of an accident-stress hypothesis, we found an increase in cancer following the accident that related to proximity of residence to the Three Mile Island nuclear plant. Cancer rates in those living nearest TMI rose in 1982, three years postaccident, remained raised for another year, and then declined. The relationship with proximity is unlikely to be explained by better case ascertainment for residents of the inner ring since, in the interests of comprehensive case-finding, we reviewed medical records at all hospitals within a 30-mile radius and at regional referral centers.

Residential proximity to the TMI plant was related to cancer rates prior to the accident as well as after, suggesting the presence of risk factors that were not sufficiently controlled by our adjustments for urbanization and social class. As a means of handling the confounding effects of unmeasured factors (e.g. cigarette smoking), we therefore adjusted for baseline risk. With this adjustment, the odds ratio for residential proximity after the accident was reduced to borderline statistical significance. Nonetheless, the postaccident pattern involving a sudden peak of excess cancers in residents near the plant does appear to be distinct from the preaccident pattern, which showed cancer rates in the inner ring to be slightly higher throughout the period.

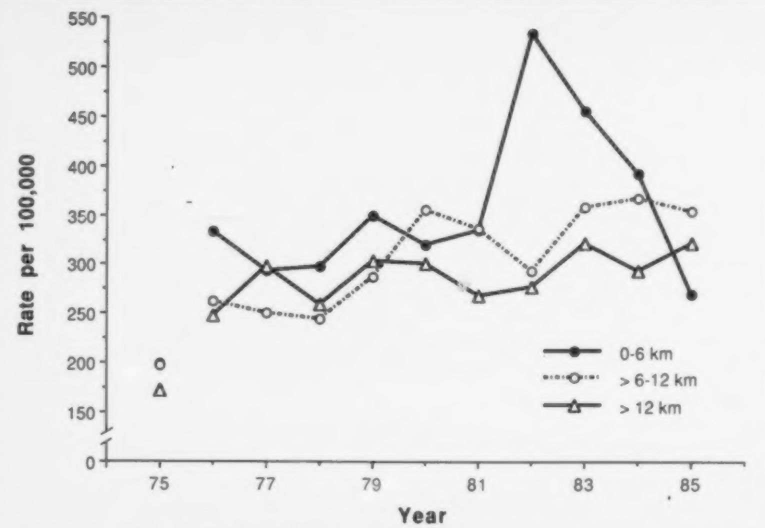

FIGURE 1—Yearly Age-adjusted Incidence Rates (100,000) of all Cancers, 1975-85, for Three Areas Defined by Distance from the TMI Nuclear Plant.

Note: In all three areas, figures were low for 1975, when hospital records were initially computerized.

Why a peak of cancer cases should arise in 1982, three years after the accident is not at all obvious. It could relate to increased cancer surveillance near the plant, particularly as the increase appears to involve several different cancer types. If residents changed their medical care habits following the accident, so that cancer was diagnosed earlier, a "screening effect" could arise, resulting in an initial inflation in cancer rates.[46] We sought and did not find consistent evidence of earlier detection near the plant in our comparison of preaccident and postaccident diagnostic trends. The absence of an increase in mortality rates—particularly for lung cancer which is rapidly fatal—may point to a screening bias, however, as may the dip in the cancer incidence rate near the plant in 1985, the last year of the study period. Distinguishing between improved surveillance, potentially stress-related, and a direct biological effect of stress is difficult with these data, particularly if, as seems likely, stress acts to accelerate the appearance of cancer rather than to initiate new cases.

In terms of a stress hypothesis, the study's major limitation is the lack of any measure of stress at the individual level. Using distance of residence from the plant to indicate stress is bound to introduce measurement error since individuals vary in both their perception of stressful events and response to them. It does seem reasonable to assume, however, that residents living close to the plant experienced more stress on average than residents living farther away. The Governor's evacuation advisory, issued two days after the accident, focused on a five-mile radius, and investigations of possible mental health consequences found that stress responses among area residents were related to distance from the plant.[4,5,9,14] In our study, however, the proximity measure is vulnerable to migration effects: inmigrants will not have been exposed to the stress of the accident but will be considered so in the analysis, and out-migrants may be self-selected for high stress levels. Given these sources of error, if stress does underlie the observed association between proximity to the plant and cancer risk, its effect could be underestimated. On the other hand, ecological associations frequently overestimate the magnitude of effects at the individual level.[47,48] Even if the stress hypothesis holds, the mechanism could be indirect. The stress of the accident could have increased exposure to behavioral risk factors, such as cigarette smoking, but we have no data with which

*Among those with known stage of diagnosis.

to evaluate this possibility. Whatever the mechanism, a true effect on cancer produced in so short a time could only manifest itself by acting on preexisting cancers.

We carried out statistical analyses to test whether the gradient in cancer risk with residential proximity—present during routine operation of the Three Mile Island plant prior to the accident, as well as after—could possibly be explained by emissions from TMI. Fitting a multivariate regression model with both measures (proximity and plant emissions modeled mathematically) actually strengthens the association of proximity with cancer incidence. Also, the pattern of rise and fall in diagnosed cancers between 1982 and 1984 would not be expected with radiation.

Conclusion

In an analysis examining cancer rates and residential proximity to the Three Mile Island nuclear plant, we observed a modest postaccident increase in cancer near TMI that is unlikely to be explained by radiation emissions. The increase resulted from a small wave of excess cancers in 1982, three years after the 1979 accident. Such a pattern might reflect the impact of accident stress on cancer progression. Our study lacked a direct, individual measure of stress, however, The most plausible alternative explanation is that improved surveillance of cancer near the TMI plant led to the observed increase. Investigations of cancer patterns in communities with future environmental incidents should consider gathering data on stress and stress-related behaviors, including change in medial care-seeking, as well as on exposure to pollutants. ☐

Acknowledgments

We are indebted to Dr. Myunghee Paik for contributions to statistical analysis, to Christine Johnsen for field work, Hung Tao for computer programming, George Colbert for cartography, and Joyce White for preparation of the manuscript. We thank the Pennsylvania State Health Data Center for providing records of cancer deaths and the 25 participating hospitals for access to records of cancer patients. The research was supported by the Three Mile Island Public Health Fund, a court-supervised fund created to address public health issues of concern to residents of the area surrounding the TMI nuclear facility; we appreciate their support.

Child Care Arrangements of American Children: NCHS Report

A recent report from the National Center for Health Statistics profiles the child care arrangements received by American Children. The report, *Child Care Arrangements*, is derived from the National Health Interview Survey on Child Health, conducted by NCHS in 1988.

The survey on child care arrangements found that two thirds of all children 5 years of age and under had been in day care at some time in their lives, with the proportion increasing with age—from 56 percent for those under age 2 to 80 percent for those 4-to-5 years old. In 1988, approximately 13.3 million children were receiving child care, including 50 percent (almost 4 million) of those under the age of 2.

Of all the children receiving child care, 83 percent had mothers who were employed. The most commonly used child care arrangements were nursery schools or preschools (used by 23 percent) and care provided by a nonrelative in a home other than the child's (21 percent). About one fourth of children receiving child care were cared for alone; 35 percent were in groups of two to three children; 20 percent with four to six children; and 23 percent in groups of seven or more.

The report *Child Care Arrangements*, prepared by Deborah A. Dawson, PhD, and Virginia S. Cain, PhD, of the National Institute of Child Health and Human Development, is available from the National Center for Health Statistics, Centers for Disease Control, US Public Health Service, 6525 Belcrest Road, Hyattsville, MD 20782; (301) 436-8500.

Effectiveness of Source Documents for Identifying Fatal Occupational Injuries: A Synthesis of Studies

Nancy Stout, EdD, and Catherine Bell, BGS

ABSTRACT

Background: The complete and accurate identification of fatal occupational injuries among the US work force is an important first step in developing work injury prevention efforts. Numerous sources of information, such as death certificates, Workers' Compensation files, Occupational Safety and Health Administration (OSHA) files, medical examiner records, state health and labor department reports, and various combinations of these, have been used to identify cases of work-related fatal injuries. Recent studies have questioned the effectiveness of these sources for identifying such cases.

Methods: At least 10 studies have used multiple sources to define the universe of fatal work injuries within a state and to determine the capture rates, or proportion of the universe identified, by each source. Results of these studies, which are not all available in published literature, are summarized here in a format that allows researchers to readily compare the ascertainment capabilities of the sources.

Results: The overall average capture rates of sources were as follows: death certificates, 81%; medical examiner records, 61%; Workers' Compensation reports, 57%; and OSHA reports 32%. Variations by state and value added through the use of multiple sources are presented and discussed.

Conclusions: This meta-analysis of 10 state-based studies summarizes the effectiveness of various source documents for capturing cases of fatal occupational injuries to help researchers make informed decisions when designing occupational injury surveillance systems. (*Am J Public Health.* 1991;81:725–728)

Introduction

Identifying all of the fatal occupational injuries in the United States work force is a difficult task that has not been accomplished with precision.[1,2] Recent literature has questioned the accuracy and completeness of ascertainment of such cases by various sources of information.[1,3–6] Death certificates, Workers' Compensation files, Occupational Safety and Health Administration fatality reports, medical examiner records, reports collected by state health or state labor departments, and various combinations of these have been used to identify cases of fatal work injuries. Each of these sources was developed for different purposes, using different definitions and methods. Because there is no universally accepted gold standard against which to compare, particularly at the national level, it is difficult to measure precisely the proportion of all fatal injuries identified by a specific source.

In a smaller geographic area, such as a state, the pool of fatal work injuries can be defined as the combination of unique cases identified through several sources. Capture rates can then be estimated as the proportion of the total pool identified by each source. This method of assessing the completeness of case ascertainment by various sources of fatal work injury data has been employed in at least 10 states. Results of these studies are summarized here to provide an indication of both the overall average capture rates of the sources, and the variation in capture rates by state.

Sources of Data

The source documents used to identify fatal occupational injuries differ in their primary purposes, methods, and target populations. The advantages and limitations of various sources have been discussed elsewhere.[1,3,7] Issues of validity, completeness, accuracy, timeliness, and the usefulness of data elements in these sources are important considerations in fatality surveillance, but are outside the scope of this paper. The sources examined here are briefly described in terms of their characteristics salient to comparing capture rates.

Death certificates and medical examiner records are the only two available sources that have the potential to identify all cases of fatal work injuries in a given geographic area. Death certificates are filed for each death that occurs in the US and follow a standard format that includes an item indicating whether the death was due to an injury sustained at work. The accuracy and consistency of this item is questionable, however, as no explicit national guidelines exist that define "injury at work."[8,9] Motor vehicle crashes and homicides at work appear to be particularly underreported as work injuries on death certificates.[7,8,10,11]

In most states, medical examiner (ME) or coroner investigations are required for deaths that are due to accidents, homicides, suicides, or deaths that occur unexpectedly.[9] In jurisdictions where ME or coroner records are computerized, or at least centralized, they are a valuable source of information.[12,13] In most states,

[e] For ME records with unclear work-relatedness, death certificates were reviewed to verify injury at work or reject false positives.

however, both ME and coroner reports exist as fragmented paper files held in various locations throughout a state, they are inconsistent among jurisdictions, and frequently do not indicate the work-relatedness of a fatal injury.[3]

Employers under Occupational Safety and Health Administration (OSHA) jurisdiction are required to report to OSHA all work-related fatalities of employees. Many of these incidents are then investigated and OSHA investigation reports are filed. Not all workers are under OSHA jurisdiction and not all incidents are investigated. Public sector employees, and self-employed workers, for example, are exempt from reporting requirements. Events such as airplane crashes, motor vehicle crashes, and homicides are investigated by other agencies, and are not routinely identified or investigated by OSHA. Recent studies also suggest substantial underreporting of fatalities that do fall under OSHA jurisdiction.[5,7,14–18]

Workers' Compensation claims can provide valuable detail about the nature of fatal injuries and accurate specification of employment. Like OSHA coverage, however, many workers are not covered by Workers' Compensation laws. Moreover, state compensation laws differ substantially so that covered worker populations are not comparable by state, and the national population of covered workers is difficult to define.

In some states, occupational fatalities are reported to the state department of labor or the state department of health. The specific types of employment and fatal events that are reported vary from state to state. For example, in Massachusetts all construction industry employers must report every accident resulting in death. The Massachusetts Department of Labor and Industries maintains records of these and other work-related fatalities reported voluntarily by employers, workers, unions, police, etc.[18]

The State Health Department source of data for the Texas study cited here refers to fatalities reported by employers participating in the Bureau of Labor Statistics (BLS) Annual Survey of Occupational Injuries and Illnesses by Industry. The survey is limited to establishments under OSHA jurisdiction, employing 11 or more workers and, as a sample survey, is not designed to capture all work fatalities.

Differences in capture rates among these sources of fatal work injury data are due in part to variation in types of employments covered by each source. Although several studies have examined capture rates of sources relative to the population covered by law to measure underreporting,[5,7,15,17] the data presented here do not address underreporting of fatal events but rather the potential of various sources to identify the universe of fatal occupational injuries.

Summary of Study Results

In each of 10 studies presented here, multiple data sources were linked, eliminating duplicate cases, to identify a total "pool" of unique fatal occupational injury cases in a state, and the proportion of that pool identified by each separate source. Table 1 summarizes the results of these studies and presents the capture rates for each source, and the range and average capture rates of the combined study results.

All 10 studies used death certificates as one source of case ascertainment and in all but two studies a greater proportion of the total pool of fatal work injuries was identified by death certificates than by any other source. The average capture rate for death certificates over all the studies was 81 percent.

Workers' Compensation files, used as a source of case ascertainment in eight states, had an average capture rate of 57 percent. The wide range (40 to 70 percent) is likely due to the different worker groups covered by the various state compensation laws.

OSHA fatality reports identified an average of 32 percent of cases. The variation in capture rates by state (21 to 42 percent) may be partially due to differences in the OSHA forms examined. In most states, first reports of fatal injuries were used to identify cases. The California[18] and New Jersey[a] studies, however, used OSHA fatality investigation reports. Since not all reported fatalities are inves-

[d] For ME records with unclear work-relatedness, death certificates were reviewed to verify injury at work or reject false positives.

tigated, first reports are likely to identify a greater proportion of deaths than investigation reports.

Two of the three studies that included ME records identified more cases from ME records than any other source.[4,10] One study used death certificates to verify injury at work for an unknown proportion of ME records on which work relatedness was not indicated; the capture rate would have been lower if ME records had been reviewed independently.[10] In the third study, ME records identified the smallest proportion of cases.[a] This range in capture rates, from 32 percent to 90 percent illustrates the magnitude of variation by state in the potential for ME records to ascertain cases of fatal work injuries.

Occupational fatalities reported to state health departments and state departments of labor under various legislation are grouped together in Table 1 for simplicity. The average capture rate, (27 percent) is presented as a rough indication of the usefulness of such reports for identifying fatal injury cases. This average, however, is based on only three studies, and substantial differences in reporting requirements limit the comparability of these data by state.

Table 2 presents the proportion of the pool of fatal injury cases identified by only one source of information in each study. The range and average sole source capture rates provide an estimate of the proportion of the universe that might be identified by only one specific source and not the others. Obversely, the average for each source presented in this table may be interpreted as the additional proportion of the total pool of cases that might be identified by using this as an additional source of case ascertainment.

These capture rates are a function of the total pool of fatalities identified in each state, and the number and types of source documents used to define that pool. The sole source averages are presented in Table 2 as crude estimates for the purpose of comparison, rather than as precise means.

Over all the studies, death certificates uniquely identified the greatest proportion of fatal work injuries (36 percent), followed by Workers' Compensation records (17 percent), and ME records (12 percent). State labor department records (5 percent) and OSHA fatality reports (less than 1 percent) contributed relatively few additional cases to the total pool.

Discussion

Generally, if surveillance is limited to one source of information, death certificates will likely ascertain a greater proportion of the universe of fatal work injuries than will the other sources examined here. For national level surveillance, death certificates are unique among these sources in their combined potential to identify all fatal work injuries, and their comparability between states. However, the accuracy and consistency with which the injury at work items on death certificates are completed varies by state. Current efforts by the Agency for Vital Records and Health Statistics (AVRHS), National Institute for Occupational Safety and Health (NIOSH), and the National Center for Health Statistics (NCHS) to increase the validity and reliability of this item could vastly improve our ability to identify the universe of fatal occupational injuries at both state and national levels.

Under some jurisdictions, ME records may provide more complete case ascertainment than other sources. However, they also show the greatest variation by state in their ability to identify cases. Efforts to computerize ME records in a consistent format are currently underway in several states. Uniform automation of ME records could substantially improve fatal work injury surveillance within states and enable interstate comparisons.

The combined results of these studies suggest that Workers' Compensation records are not a useful sole source for case ascertainment of work fatalities. As a supplemental source, however, Workers' Compensation records could be expected to add the greatest proportion of cases to a vital records-based system. OSHA fatality reports have limited utility in fatal injury surveillance. Alone, they might be expected to identify about one-third of all cases and, as an additional source, they might capture an additional 1 percent of cases.

Because the definition of state health department and state labor department fatality reports varies so widely by state, generalized conclusions about this source cannot be drawn. In developing surveillance systems, the state-specific characteristics of this potential data source should be considered.

The combined results of these studies highlight several salient points regarding fatal work injury surveillance. The most prominent of these is that using multiple sources of data will always result in more complete case ascertainment than using one source alone.

The value added by including a subsequent source for case ascertainment depends on which source is added and its characteristics within that geographic area. For example, using state labor department records in addition to death certificates in Michigan improved case ascertainment by 14 percent.[20] In the Massachusetts study, however, where three other sources were also used and where Department of Labor reports had limited coverage, only 2 percent more cases were identified by these records.[18]

In addition to the sources discussed here, other sources should be considered to fill gaps in surveillance systems. For example, all of these sources tend to underreport occupational motor vehicle fatalities and likely undercount homicides. Police report forms and Highway Traffic Administration reports could be valuable in identifying such cases, if efforts were made to include an indication of work-relatedness on these reports.

When designing and developing fatal occupational injury surveillance efforts, cost-benefit analysis and value-added formulas are often considered to determine which sources of data will provide the most effective results given study objective and resource limitations. It is hoped that this synopsis of studies will help researchers make informed decision when designing surveillance systems, recognize limitations of various sources, and support improvements to existing sources so that we might all better understand the magnitude and nature of fatal occupational injuries in the United States. ☐

Female Homicides in United States Workplaces, 1980–1985

ABSTRACT

Background: Women, while noted for low occupational injury mortality rates, are more likely to die as victims of assault than from any other manner of injury at work.

Methods: From the National Traumatic Occupational Fatality surveillance data, 950 women were identified who were fatally assaulted at work. Homicide rates were calculated for the demographic and employment characteristics of these women. Risk ratios among types of lethal injuries were examined.

Results: During 1980–1985, the crude six-year workplace homicide rate was 4.0 deaths per million working women: one twentieth the homicide rate of the US female population. Decedents ranged from 16 years (the lowest age included in the data base) to 93 years of age. Working women older than 65 years had the highest age-specific homicide rate, 11.3 per million. Women younger than 20 had the lowest, 2.5 per million per year. Homicide rates for women of races other than White were nearly twice as high as those of Whites.

The leading causes of death were gunshot wounds (64 percent), stabbings (19 percent), asphyxiations (7 percent), and blunt force trauma (6 percent). Nearly 43 percent of the deceased women had been employed in retail trade: 8.7 per million employed women annually.

Conclusions: During 1980–1985, only 6 percent of the nation's victims of work-related injury deaths were female: 41 percent of those women were murdered. Homicide is currently the leading manner of traumatic workplace death among women in the United States. (*Am J* Public Health. 1991; 81:729–732)

Catherine A. Bell

Introduction

Injury surveillance conducted by the National Institute for Occupational Safety and Health (NIOSH), Division of Safety Research, has shown that from 1980 through 1985, homicide was the third leading manner of workplace death in the United States, surpassed only by motor vehicle crashes and machine-related fatal injuries. Nearly 13 percent of all occupational injury deaths were homicides. During 1980–85, 47 percent of the United States work force was female,[1] yet only 6 percent of the nearly 7,000 annual fatal work-related injuries were suffered by women: 41 percent of these women were homicide victims.[2]

Two state-based studies have shown that homicide is a prominent form of lethal occupational injury among women. In a study of fatal work-related injuries in Texas, 1975–80, 53 percent of the 348 women were murdered.[5] Only 13 percent of the fatally injured men were homicide victims.[6] The occupational homicide rate for women was one-third that for men: 7 per million employed women per year compared to 21 per million employed men. In California during 1979–81, the rate of work-related homicide among employed women was 5 per million compared to 22 per million among men.[7] Both studies showed that while a woman was at lower risk of being murdered at work than a man, a greater proportion of female traumatic occupational deaths were due to homicide.

Recently, NIOSH began using demographic and injury event information from state death certificates to examine US fatal occupation injuries, including homicides. This report describes the female victims of work-related homicide during 1980–85, as reported to the National Traumatic Occupational Fatality (NTOF) surveillance system.

Methods

The NTOF data base is composed of death certificates from all state vital statistics reporting units in the US that meet the following criteria: 1) age at death—16 years or older; 2) a positive response to the "Injury at Work" item; and 3) an external cause of death (International Classification of Diseases, Ninth Revision, E800-E999). The methods and limitations that pertain to NTOF injury surveillance are described fully elsewhere.[8]

All NTOF records of female deaths from 1980 through 1985 that reported homicide as the manner of death were selected for this analysis. Homicide, death due to injuries purposely inflicted by another person, was identified using the element in Part II of the death certificate that queries "Accident, Suicide, Homicide, or Pending" because not all NTOF records had coded cause of death information at the beginning of the study. No effort was made to exclude deaths due to legal intervention. Recording practices in Louisiana, Nebraska, New York, and Oklahoma prevented identification of work-related

[b] Deaths per 1,000,000 workers.

intentional injuries over the study period, so homicide data from these four states were not available.

Employment information was coded from the "usual" industry and occupation entries on the certificates. The Standard Industrial Classification[9] system was used to categorize usual industry of employment. Occupation information was coded into major groups with the 1970 Bureau of Census Classifications for deaths in 1980 through 1982 and the 1980 Bureau of Census Classifications for deaths in 1983 through 1985. The two coding schemes ensured agreement between incidence and underlying employment information because the source of the population data used in the rate calculations changed coding schemes in 1983.[10,11]

To calculate mortality rates, the Annual Summaries of EMPLOYMENT AND EARNINGS[12] provided denominator data for the US. The GEOGRAPHIC PROFILE OF EMPLOYMENT AND UNEMPLOYMENT[13] was used to correct the denominator data used in age-, race-, and employment-specific rates by excluding the estimated work force of the four states which did not provide homicide data to NTOF (nearly 10 percent of the female work force of the US).

Homicide frequencies and annual and six-year mortality rates were calculated for demographic and employment characteristics. Victims whose occupations or industries of employment were unclassifiable were not included in employment-specific rate calculations, although they were included in all other rates. Age- and race-specific rates were estimated. Race-specific rates were calculated for Whites (including Hispanics), Blacks, and Others (Asians and American Indians). Definitive employment data were not available for Hispanics, Asians, or American Indians. Risk ratios (RR) contrasting types of injury (e.g. firearms versus not firearm) within racial subsets were estimated.

Deaths assumed to involve close physical contact, such as stabbing or beating, were compared to those resulting from gunshot wounds that could be inflicted from a distance. Two categories of close physical contact deaths were defined: multiple stabbing and a broader category that included all rape, stabbing, slashing, blunt force, and manual asphyxiation deaths. These were contrasted to the gunshot wounds through risk ratio estimates. Ninety-five percent Taylor Series confidence intervals were constructed around all risk ratio estimates.[14]

Results

NTOF data described 950 women who were murdered at work during 1980–85 (Table 1). The women's ages ranged from 16, the youngest documented in NTOF data, to 93 years. The six-year age-adjusted homicide rate was 4.5 deaths per million working women. The highest homicide rate, 11.3 per million, was among working women 65 years of age and older (Table 2).

Black women were 1.8 times more likely to be killed than Whites. The RR for homicide among Blacks contrasted to all other women was 1.7 (95% CI: 1.4, 2.0) and for the Other racial category was 1.9 (95 % CI: 1.4, 2.5). Hour of injury was reported for 680 cases: homicides were most frequent between 4:00 and 5:00 pm. However, 30 percent of the women were murdered between 6:00 pm and midnight and 69 percent died between 3:00 pm and 7:00 am.

Industry of Employment

Nearly 43 percent of the homicide victims were employed in the Retail Trade Industry which also had the highest six-year homicide rate, 8.7 per million retail employees. Forty-one percent of these women worked in food stores, and 34 percent in eating and drinking establishments.

The Transportation, Communication, and Public Utilities Industry had the second highest rate, 4.0 per million: 34 percent were employed in motor freight transportation and warehousing and 18 percent in local passenger transportation with buses and taxis. While 23 percent of the women worked in the Service Industry, their homicide rate was quite low, 2.22 per million: 22 percent of these women worked in education, 16 percent in health services, and 13 percent in hotels, motels, and other lodging.

In Public Administration, 33 percent of the women were employed in justice, public order, and safety, 28 percent in general government, and 23 percent in the military. Industry of employment was not coded for 14 percent of the decedents, due to lack of specific employment information on the death certificates (Table 3).

Occupation

Despite the changes in the occupation classification schemes in 1983, 71 percent of the murdered women were employed in only four occupational groups: sales personnel (n = 184), clericals (n = 169), service employees (n = 182), and supervisors (executives, managers, and administrators) (n = 151). During 1980-82, retail store clerks and cashiers, classified as clericals, accounted for 26 percent of the decedents' occupations: their homicide rate was only 3.4 per million. Sales workers, such as sales clerks and owners of retail establishments, died at a rate of 8.3 per million. During the next three years, retail clerks and cashiers were classified as sales occupations. These accounted for 27 percent of the 1983–85 deaths with a three-year rate of 7.6 per million.

For the six-year period, 105 of the 175 women in service occupations were employed in eating and drinking establishments. At least 52 of these worked in bars, taverns, or lounges. Nineteen women were employed as law enforcement officers or security guards. Lack of national

[b] Deaths per 1,000,000 workers.

estimates for employment in these specific occupations made rate calculations impossible.

Employment as a supervisor increased a woman's risk of homicide. Decedents most commonly managed restaurants, apartment complexes, or retail establishments. Ten percent of the women owned their own businesses.

Region

Only 24 (3 percent) of the women were murdered outside the states where they resided. Despite the lack of reporting from Louisiana and Oklahoma, over half (52 percent) of the murders took place in the South at a rate of 5.7 per million women working in the reporting states. The Western states had the second highest rate, 4.1 per million, and 23 percent of the homicides. The North Central states, where Nebraska deaths were not reported, had a homicide rate of 2.5 per million and 18 percent of the deaths. Only 7 percent of the fatalities were reported from the Northeast at a rate of 1.2 per million. This region's figures are seriously compromised by the omission of New York deaths from the data. Of the 46 states reporting, rates indicated that women were at highest risk of being murdered at work in Nevada, Mississippi, the District of Columbia, Florida, and Texas.

Method of Homicide

Firearm injuries caused 609 deaths (64 percent): 148 (16 percent) noted multiple gunshot wounds. Stabbing and slashing caused 181 deaths (19 percent). Multiple stabbing was mentioned in 103 cases (11 percent). Decedents were asphyxiated in 69 (7 percent) or died from blunt force injuries in 57 (6 percent) of the cases. Together, fires, explosions, motor vehicle impacts, poisoning, and sexual assault were reported in fewer than 4 percent of all cases.

Lethal gunshot wounds were most frequent in the 25–54 year age range. The firearm homicide rate among Black females averaged 4.4 per million compared to 2.2 per million among Whites. Black women were slightly more likely to die from gunshot than other wounds (RR, 1.1, 95% CI: 1.0, 1.2). The risk of Hispanic women dying from firearm relative to other injuries (RR) was 1.4 (95% CI: 1.2, 1.6).

Multiple stabbings were prominent, but not significantly elevated, among the oldest women. However, the risk of an elderly woman dying from any form of physical contact relative to gunshot wounds (RR) was 3.6 (95% CI: 2.6, 4.9). Asian and American Indian women were slightly more likely to be killed in trauma involving physical contact than from gunshot wounds (RR of 1.4, 95% CI: 1.0, 2.0), while Black women were more likely to die from gunshot wounds (RR = 0.7, 95% CI: 0.5, 0.9).

Discussion

While the limitations of death certificate information in general[15–18] and NTOF in particular[8] have been well defined, a few merit discussion in terms of occupational homicide surveillance. Surveillance based on death certificates alone underreports cases of fatal occupational injuries. State studies have shown between 67 percent and 88 percent of all traumatic workplace deaths can be identified using death certificates alone.[19] Legal sources such as police files and medical examiner records are more detailed; however, they do not regularly identify work-related cases and are not readily accessible in most US jurisdictions. Death certificates provide systematic accounts of each traumatic death in the US, and not those reported to have occurred at work. Death certificates record "usual" occupation and industry of employment, not necessarily employment at the time of injury. Studies show that between 64 percent and 74 percent of reported usual occupations correspond with decedents' most recent occupations, and between 60 percent and 76 percent of the usual industry entries correspond with most recent industries of employment.[16-18]

Both formal state policies and individual practices affect case ascertainment and data accuracy. The most notable weakness is lack of standard criteria for completing the injury at work item; it is not rigorously defined and is subject to interpretation. For example, in Louisiana a state policy existed where "injury" was interpreted as "accidental injury." Until 1985, the injury at work item was not completed for intentional injuries. Even when injuries that take place at work are correctly recorded, some states automate that information only for unintentional injuries. In these states all homicides and suicides must be screened to find each noted as having occurred at work. This screening is tedious and through human error intentional injury cases may be missed.

A certifier may also impose an idiosyncratic definition of work that excludes or obscures employment. No prostitutes or illicit drug dealers are identifiable in the NTOF data. Juveniles are rarely considered "at work." Deaths perpetrated by acquaintances or family members may be screened by a certifier who considers "at work" to mean solely work-related. Homicides are also misclassified as accidents, suicides, or deaths of undetermined cause. For such reasons, the cases here underreport victimization among working women in the US.

While such factors can hinder hazard identification and ultimately injury control, NTOF surveillance rapidly identified homicide as the major occupational hazard for the nation's women. Homicide risk may be associated with exposure to the public, the exchange of money, and evening employment.[5–7,20] Women employed in the retail industry, particularly in food stores, were at greatest risk. Many owned or managed groceries, taverns, and restaurants. Elevated homicide rates in motor freight and warehousing, local passenger transportation, government, and law enforcement call for heightened safety for workers in these jobs. Detailed studies of homicide risk in education, health services, hotels, motels, and other lodging places are also warranted.

The role of victim age in these deaths is still not clear. Older women may be attractive targets and/or less likely to survive traumatic assault. This analysis also showed that older women were often self-employed or small-business owners. While Davis, *et al*, argued that high workplace homicide rates in Texas women age 65 years or older did not result from underenumerated employment,[5] the person-year denominators used in the NTOF age rates may distort the risk estimates. For example, low rates among young women may reflect part-time work. Age-specific homicide rates should be examined using hour-based employment information when available.

Most of the women died from gunshot wounds. Close physical contact deaths were significantly elevated among older White women and among Asians, a group generally noted for low risk of violent death.[21] Because control strategies may depend on discrimination between robbery assault and personal or sexual violence, more detailed studies are needed on the circumstances of workplace homicides.

At least one major convenience store chain has implemented robbery deterrence programs which couple behavioral and environmental components.[22] In evaluated programs, employees have been trained in techniques of conflict resolution and nonviolent response.[21–24] Locked drop-safes, well-lit parking lots, and a work area openly visible to the public are environmental components that appear to reduce robbery and associated mortality.[22]

Convenience stores are essentially small businesses with control strategies that might prove useful in small, owner-operated businesses. Before recommending use of their control strategies developed in other environments, performance in the new environment should be rigorously evaluated.

Hazardous industries may also benefit from regulation, particularly where employers have not reduced homicide risk. The Occupational Safety and Health Administration (OSHA) standards do not yet explicitly address safety from workplace violence, but an increasing number of local ordinances mandate hours for store operation or the presence of multiple employees. The next step in reducing the risk of workplace homicide is to evaluate the effectiveness in various work settings of existing as well as new control strategies. □

Occupation, Industry, and Fatal Motor Vehicle Crashes in 20 States, 1986–1987

ABSTRACT

Background: Motor vehicles are a leading cause of injury on and off the job.

Methods: To describe the occurrence of fatal motor vehicle crashes in the working-age population, a case-control study was conducted among persons 15–64 years old who died in 1986 or 1987 in any of 20 states reporting death certificate occupational data to the National Center for Health Statistics. Cases were occupants of motor vehicles (excluding motorcycles) who died of injuries sustained in a crash (E810-E825, 9th revision International Classification of Diseases), and controls died of any other cause.

Results: Transportation-related occupations had more than the expected number of deaths for men (odds ratio = 1.6, 95% confidence interval = 1.4 – 1.9) and women (odds ratio = 2.1, 95% confidence interval = 1.0 – 4.5), as did managerial occupations (odds ratio = 1.3 and 1.7, 95% confidence interval = 1.1 – 1.5 and 1.3 – 2.2 for men and women, respectively). Men in mining and oil drilling occupations and the wholesale trade industry also had excess crash deaths. Among women, additional excesses were observed among professional specialists and in several groups with few deaths, including agriculture, construction, and the military, whereas homemakers had markedly fewer vehicle crash deaths than expected.

Conclusions: These findings encourage further investigation of this important safety hazard, but also call attention to a need for more detailed studies and improved data. (*Am J Public Health.* 1991;81:733–735)

Introduction

Motor vehicles cause more fatal occupational injuries in the United States than any other agent.[1] Previous studies providing data on this problem have focussed on single states or selected occupational groups,[2-6] but this investigation, using death certificate data from the National Center for Health Statistics, was undertaken to provide a description of the overall epidemiological pattern of motor vehicle-related fatalities in the United States working population to be used in planning future research and prevention efforts.

Methods

The subjects of this study were residents of 20 states (Alaska, Colorado, Georgia, Indiana, Kansas, Kentucky, Maine, Missouri, Nevada, New Hampshire, New Mexico, North Carolina, Ohio, Oklahoma, Rhode Island, South Carolina, Tennessee, Utah, Vermont, and Wisconsin) who died in 1986 or 1987. Only these states coded occupation and industry data from death certificates and reported them to the National Center for Health Statistics (NCHS) in at least one of those two years. Occupation and industry coding are done by the states according to the 1980 US Census Bureau occupation and industry classification system.[7]

Subjects were selected from 1986 and 1987 mortality data tapes from NCHS. All 5,031 men and 1,776 women 15–64 years old who died of injuries received as drivers or passengers in crashes of motor vehicles other than motorcycles (coded E810-E825 with 4th digit equal to 0 or 1 according to the International Classification of Diseases, 9th Revision), and who had an occupation other than "student," "volunteer," "never worked," or "retired" on the death certificate were selected as cases. A control group of 7,167 men and 4,369 women was formed by selecting a 5 percent simple random sample of deaths from all causes other than motor vehicle crashes from the same NCHS tapes using restrictions identical to those applied to the cases.

Standard case-control odds ratios were computed by treating each occupational category in succession as the "exposed" group, and all other categories combined as "unexposed."[8] The odds ratios can be interpreted as the ratio of the observed number of motor vehicle crash fatalities in each occupational category to that expected based on the experience of all others.[9] Age-adjusted odds ratios were estimated by the Mantel-Haenszel method, and test-based confidence intervals were computed for both the crude and adjusted estimates.[8] Because female homemakers were the largest single occupational group, they were considered separately using all women with employment outside the home as the unexposed referent, but were excluded from all other analyses involving women.

Results

Occupation

Crude and age-adjusted odds ratios for motor vehicle crash fatalities by occupation are shown in Table 1. Without adjustment for age, men in white collar oc-

[a] Excludes homemakers.

cupations, except for technicians and related workers, tended to have essentially the expected number of crash deaths or somewhat fewer, whereas most blue collar occupations had a small excess of deaths. With age adjustment, "extractive" occupations (miners and oil well drillers), and transportation and material moving occupations had the highest odds ratios, with 1.8 and 1.6 times more deaths than expected, respectively. Executives, administrators, managers, and sales workers had more modest excesses of deaths.

For women employed outside the home, some of the largest excesses of vehicle crash fatalities occurred in occupations with relatively few deaths, notably construction trades, transportation, agriculture, and the military. Odds ratios were also elevated, although to a generally lesser degree, in more populous categories, including managerial occupations, professional specialists, and technicians. Female homemakers had very low crash mortality compared to women with paid employment.

Industry

Odds ratios indicating the association of motor vehicle crash deaths with Census Bureau industry categories are shown in Table 2. Among men, most industries had essentially the expected number of crash deaths. However, the categories of transportation, communication, and utilities and wholesale trade had 40 percent more deaths than expected when adjusted for age.

Construction, followed by transportation, communication, and utilities, were the industrial categories with the largest excesses of crash fatalities among women employed outside the home, with about three and two times the expected number of cases, respectively. The more modest excess of deaths among women in the finance, insurance, and real estate category may be more quantitatively important given the larger number of deaths in that group. Public administration and personal services are populous categories with substantially fewer deaths than expected. Crude and adjusted odds ratios tended to be similar except for the military category, for which the odds ratio declined sharply with adjustment for age.

Discussion

This 20-state mortality study describes patterns of motor vehicle crash fatality for men and women by occupation and industry. Such information has not been available before for a geographically diverse population including a wide spectrum of occupations. The vital statistics data used in this study offer several advantages for identifying groups of workers at increased risk: death registration is complete, comparability of data between cases and noncases is assured, and large studies including many states and all occupational groups can be done at minimal cost. On the other hand, studies of this type share generic limitations of design and data quality which have been discussed elsewhere.[9-11]

The major interpretational challenge of this study is that the data do not allow injuries which occurred while the decedent was working to be distinguished from those which occurred during other activities. To minimize the proportion of nonworkers in the study, only individuals ages 15 to 64 years with an identifiable occupation indicated on their death certificate were included. However, deaths due to injuries which did not occur at work were also necessarily included, because the states do not report to NCHS the death certificate field that identifies on-the-job injuries.[10] A field coded for the place of injury (for example, industrial place, home, or farm) is available from NCHS public data, but it does not appear to effectively distinguish occupational injuries.[12]

Although it would be helpful to separate injuries which occur on the job from those taking place elsewhere, the ability to do so is not central to all potential uses of these data. The present analysis based on occupational groups also approximates the socioeconomic pattern of motor vehicle crash mortality. In addition, the data are relevant to injury prevention efforts, because some programs directed toward workers, like the Occupational Safety and Health Administration's proposed workplace driver training program,[13] have the potential to reduce injury risk both on and off the job. Accurate identification of mortality excesses due to on-the-job hazards remains important for more specific interventions, such as equipment modifications, however.

In spite of some disadvantages, the data used in this study appear to be sensitive enough to capture previously-observed excess vehicle crash mortality among transportation workers.[2,6] This should lend some confidence to the interpretation of the occupational patterns of mortality which emerge from these data. Comparison of the crude and age-adjusted odds ratios may also be useful for interpreting the variation in mortality among different groups of workers: the adjusted odds ratios should most accurately reflect the inherent hazardousness of a job, while the crude measures are also sensitive to the sociodemographic composition of the workforce.

Because of the large number of injuries and deaths due to the use of motor vehicles in work, these hazards should be a priority for injury research and prevention. This study suggests that further investigation of managers and other seemingly low-risk groups, in addition to transportation workers, might be warranted. However, the availability of appropriate data remains an obstacle. Uniform coding of the death certificate indication of injury at work and its inclusion in NCHS public mortality data would improve future surveys based on those data, but studies using more detailed information on individuals and vehicles used for work are also needed to identify factors which could be modified to prevent motor vehicle injuries to workers. □

An Analysis of Occupational Blood Lead Trends in Manitoba, 1979 Through 1987

Annalee Yassi, MD, MSc, Mary Cheang, MMath, Milton Tenenbein, MD, Geoffrey Bawden, Jerry Spiegel, MA, MSc, and Ted Redekop, MD

ABSTRACT

Background: While regulations for workplace lead exposure become more strict, their effectiveness in decreasing blood lead concentrations and the method by which this is attained have not been evaluated.

Methods: An analysis was conducted of 10,190 blood lead samples from employees of 10 high-risk workplaces collected in Manitoba, 1979–87, as part of regulated occupational surveillance.

Results: A significant decrease in blood lead concentrations was observed overall as well as for each individual company. A 1979 government regulation to reduce blood lead to below 3.38 μmol/L (70 μg/dl) was followed by a drop in blood lead concentrations; a 1983 order to reduce blood leads to below 2.90 μmol/L (60 μg/dl) was not followed by such a drop. Longitudinal analysis by individual workers suggested that companies were complying by use of administrative control, *i.e.*, removing workers to lower lead areas until blood lead levels had fallen, then returning them to high lead areas.

Conclusion: Focusing upon blood lead as the sole criterion for compliance is not effective; regulations must specifically require environmental monitoring and controls. Biological surveillance serves as "back-up" to environmental surveillance and this database illustrates the usefulness of a comprehensive centralized surveillance system. (*Am J Public Health*. 1991;81:736–740)

Introduction

Although lead poisoning has been documented since antiquity, occupational lead intoxication continues to occur.[1–3] Moreover, there is growing consensus that lead causes toxic injury to humans at levels of exposure that only a decade ago were thought to be safe. As Landrigan notes,[1] these subclinical changes represent truly harmful outcomes and are not merely homeostatic or physiologic "adjustments" to the presence of lead.

The US Occupational Safety and Health Administration (OSHA) standard, since 1978, has required the removal from exposure of workers who have confirmed blood lead levels of 2.9 μmol/L (60 μg/dl) or higher, an average of 2.4 μmol/L (50 μg/dl) or higher on three tests, or a medical condition contraindicating continued exposure to lead. Once removed, workers cannot return to a job where they will be exposed to lead until the blood lead level is 1.93 μmol/L (40 μg/dl) or less or the employee no longer has a medical contraindication to lead exposure.[2] Environmental monitoring is also required, to ensure a permissible exposure limit of 50 μg/m.[3]

Evidence is lacking as to the effectiveness of any regulation with respect to lead poisoning. While some states maintain heavy metal registries, these only required the reporting of blood lead concentrations above 1.93 μmol/L (40 μg/dl) (until recently when some states dropped their required reporting level to 1.21 μmol/L [25 μg/dl]). Hence, longitudinal follow up of individuals, as well as by workplace, is not possible.

Manitoba, a Canadian province with a population of one million, has a list of high-risk workplaces that are under government surveillance, as well as a centralized provincial laboratory where all occupational blood lead samples are analyzed. With over 11,000 blood lead concentrations recorded in this data base for more than a decade, linked by individual as well as by workplace, it is possible to evaluate trends in the province overall, as well as by individual company. It is also possible to assess concurrent turnover or rotating of staff (administrative controls). Utilizing this blood lead data base, we address specifically the following questions:

- What is the extent of occupational lead intoxication?
- Have mean blood lead concentrations decreased following government improvement orders and tighter standards?
- What has been the role of administrative measures and engineering controls in any such decrease?

Methods

Lead Measurements

A total of 10,190 blood lead tests were performed as a result of regulatory sur-

veillance reported from 10 high-risk workplaces. Five workplaces had regular medical monitoring programs throughout the period 1979–87 inclusive, and five conducted comprehensive and continuous programs for at least two years during this period. In other workplaces the medical monitoring was sporadic and voluntary. All blood lead analyses were conducted at the provincial government's Technical Services Laboratory located in Winnipeg, Manitoba. The laboratory is accredited by the American Industrial Hygiene Association and participates in the Blood Lead Proficiency Testing program of the Centers for Disease Control in Atlanta, as well as the program conducted by the Centre de Toxicologie in Quebec. Blood leads are analyzed using the Fernandez Method.[4]

Those whose blood lead concentrations exceeded 2.41 μmol/L (50 μg/dl) on at least one occasion, had an annual frequency of testing ranging from one to 21, median of four and mode of four, whereas those whose blood lead concentrations were always less than 1.93 μmol/L (40 μg/dl) had an annual average testing frequency ranging from one to nine, with median of one and mode of one. To adjust for this variation, a quarterly median was taken for each individual. If an individual had only one blood lead test in a given year, the same result was entered in all four quarters for that year. If an individual had blood tests monthly, only the median of each quarter was entered for analysis.

As measures of blood lead concentrations tend to be skewed, most of the analyses were smoothed (using a median quarterly or annually as the case may be) and the overall medians analyzed. Contingency table analysis allowed the comparison of aggregated distributions of blood lead concentrations, while linear regression analysis assessed company trends over the nine-year period, and Mantel-Haenszel trend tests evaluated specific target proportions over shorter time segments (i.e. proportion of values over 70 μg/dl during the three years following 1979 and proportion over 60 μg/dl in the three years following 1983).

To gain insight into the mechanism underlying the longitudinal variations of individual blood lead concentrations, first order auto correlations to assess the influence of one result on the next among individual workers and testing the run of signs of first differences for randomness to assess individual patterns were performed.[5,6] The overall effect of administrative controls as hypothesized by a negative association between last blood lead concentration nearing the target level and current blood concentrations was tested using the Mantel-Haenszel chi-square stratified by regulatory period.

Industrial hygiene observations and measurements were gleaned from the records of the provincial government's workplace safety and health inspectorate.

Occupational Lead Exposure and Regulatory Process

Workplace safety and health is a provincial responsibility in Canada, with each province enacting its own legislation and regulations. The Workplace Safety and Health Act in Manitoba, proclaimed in 1977, empowers the minister to issue an order requiring an occupational health service at designated workplaces, with penalty of fine for noncompliance. This permitted the minister in charge of occupational health for the province to issue an order to five companies in 1979 to reduce blood lead concentrations to below 3.86 μmol/L, (80 μg/dl). There was no mention of environmental monitoring in the order. An individual was to be removed from the plant when his blood lead concentration exceeded 3.86 μmol/L or transferred to a low lead exposure area when the blood lead ranged from 3.38–3.86 μmol/L (70–80 μg/dl). In 1983, after considerable debate, the 1979 order was revised reducing the blood concentration removal level to 3.35 μmol/L (70 μg/dl), with workers to be transferred to low lead areas when the blood concentration ranged from 2.90–3.38 μmol/L (60–70 μg/dl). There was no mention of differential levels for women, or of environmental monitoring.

The five firms that received this order consisted of one battery manufacturer, two primary lead-using industries, one secondary lead smelter, and one combined battery breaking/secondary smelter operation. These companies all operated continuously from 1979 to 1987 with the exception of the combined battery breaking/secondary smelter operation which was shut down briefly for economic reasons during 1983. Three other companies conducted biological monitoring over part of the same period; a primary copper smelter with additional production of zinc and lead concentrate (1982–87), a battery breaking operation in a reclamation yard (1985–87), and an aluminum forging operation (1985–86) with incidental lead exposure.

In 1986 following years of controversy and no written policy, the Workers' Compensation Board (WCB) in Manitoba essentially established a blood lead concentration of 2.41 μmol/L (50 μg/dl) as a compensable level.[7] Sixty-three claims for lead poisoning had been allowed by the Manitoba WCB prior to 1986; 54 were allowed in the two years following this policy statement.

Results

Table 1 contains the 10,190 blood lead concentrations of employees who worked in the 10 designated plants between 1979 and 1987 inclusive. The proportion of values over 3.86 μmol/L (80 μg/dl) has steadily decreased; there is a statistically significant difference in the distribution of lead concentrations over the years, ($p < .0001$). There were no essential changes in this distribution when one entry per quarter for each worker is included regardless of the number of tests performed on that worker during that particular year (data available from author on request). Figure 1 illustrates the trends in median blood lead concentrations over time in each of the five companies that operated throughout this period (with the exception of a brief plant closure in 1983 in one). Median blood lead levels by year and type of plant are given in the Appendix.

A separate analysis was conducted to assess the proportion of blood lead concentrations over 3.38 μmol/L (70 μg/dl) in the three years following the 1979 order which required a reduction to below this level. Both the overall trend as well as the trend within each of the five firms subject to this order showed a highly significant decrease in the proportion of blood leads over this level (overall from 7.9 percent in 1979 to 0.8 percent in 1982). When a similar assessment was done for the 1983 order, only one of the then six companies showed a statistically significant decrease in proportion of blood leads over 2.90 μmol/L (60 μg/dl), the new target level (data available from author on request). Two companies, a secondary smelter and a combined battery breaking/secondary smelter operation, which had 11.2 percent and 11.8 percent of blood levels over 2.90 μmol/L (60 μg/dl), respectively, at the time of the 1983 order, had 13.9 percent and 16.9 percent over 2.90 μmol/L (60 μg/dl), respectively, three years later.

Industrial hygiene investigation revealed that after the first government intervention, some hygiene and/or engineering controls were implemented in all of the firms in question with each firm adopting a unique strategy depending on its condi-

tion. Thereafter, companies seemed to be making greater use of administrative controls, i.e. removing workers to lower lead-in-air areas when blood lead concentrations approached the action level, only to return them to the higher areas after their blood lead concentration had fallen. Industrial hygiene inspections found for example, that while the lead-in-air levels had dropped from 300 µg/M^3 to less than 150 µg/M^3 in a primary lead using company, between 1979 and 1983, such a decrease was not observed in the inspection of a secondary lead smelter where environmental levels continued to exceed 300 µgm/M^3. A second secondary smelter demonstrated a reduction of near 150 µg/M^3 on average but some areas, notably the furnace area, demonstrated no substantial reduction in air-borne lead with concentrations approaching 400 µg/M^3 and personal protection being used as a protective strategy. No ongoing environmental or personal monitoring programs were in place and government monitoring was generally complaint-based. Environmental data are thus incomplete.

To further investigate the apparent failure of the 1983 order to produce a continuing decrease in blood lead concentrations, longitudinal analysis was performed for all workers who ever had values of 2.90 µmol/L (60 µg/dl) or greater. A graph for these workers individually showed a marked "titration" pattern, indicating use of administrative controls. Figure 2 shows two typical examples of this pattern. It demonstrates that as a worker's blood lead concentration approaches the action levels he is removed to a lower lead area, and after his blood lead concentration falls, he is probably returned to a higher lead-in-air concentration since his blood lead level rises. This titration pattern in individual workers was present throughout the period of data collection. Its existence was further demonstrated by the significant (p = 0.0001) finding that if a worker's blood lead was less than 2.41 µmol/L (50 µg/dl) his next blood lead would be higher and vice versa. This indicates that an overall decrease in lead exposure in the plant was not occurring because the lead exposure was being averaged over a pool of employees. Four of the eight companies still in operation in 1985 had 18–50 percent of blood lead concentrations over 2.90 µmol/L (60 µg/dl); one other company brought its percentage down to 1.9 percent, while the remaining three companies had had less than 1 percent even prior to the 1983 order. The workforce turnover rates were higher in the four companies with poor compliance than in the four with lower proportion of concentrations over 2.90 µmol/L (60 µg/dl) (data available from author on request). There was much less evidence of titration in the four with better compliance (data available from author on request).

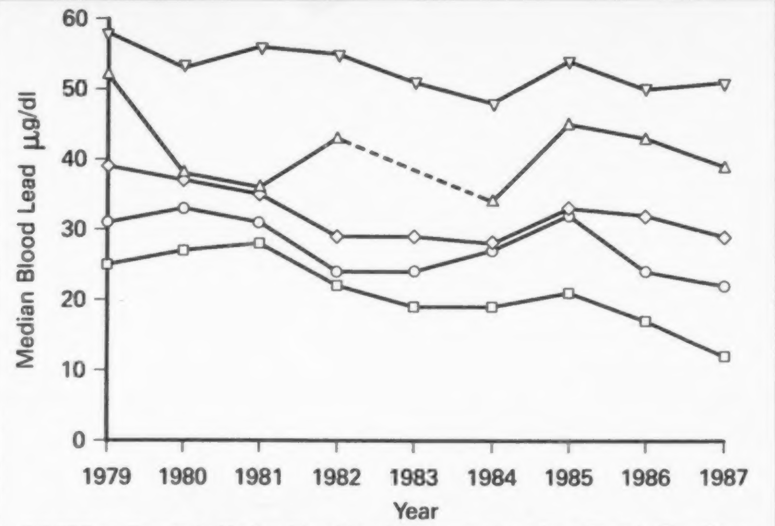

FIGURE 1—Trends in Median Blood Lead Concentrations Over Time in Five Companies Operating during 1979–87

Discussion

The prevention of lead poisoning requires: 1) knowledge of dose response relationships with establishment of an acceptable target blood lead "threshold" to reduce the potential for subclinical lead toxicity, 2) effective surveillance of the environment and of the at-risk population, and 3) action to reduce lead exposure at the source. Considerable knowledge exists with respect to "threshold" levels of exposure for different adverse effects, as summarized elsewhere.[2] There is a need to intensify the monitoring of lead levels in the at-risk population in order to take action which would result in a safer workplace. Methods used to monitor trends of occupational illness and injury[8–13] are usu-

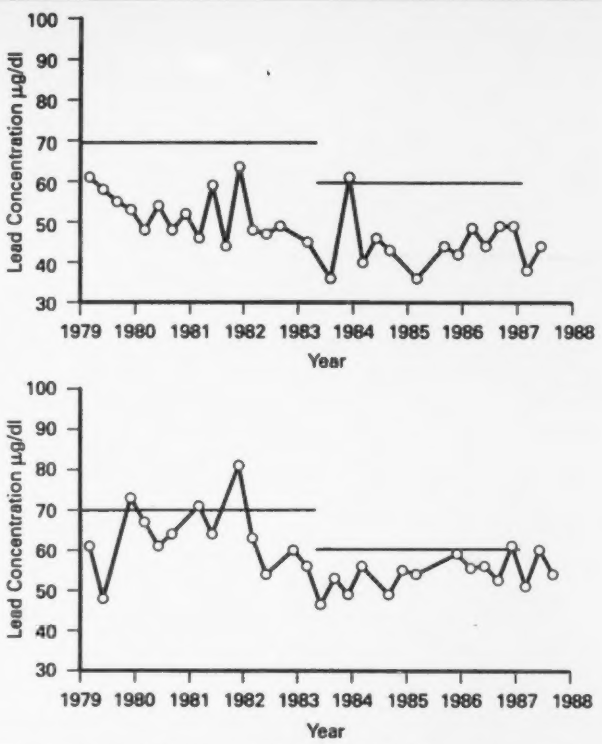

FIGURE 2—Blood Lead Concentrations in Two Individual Workers 1979–87

ally developed primarily for other purposes, making them less useful for occupational health surveillance. Most states have reporting systems specifically for occupational disease,[9] but the completeness of reporting is rarely satisfactory due to a lack of effective centralized monitoring, and disincentives for physicians and others to report occupational disease.[8,9]

One of the main purposes of surveillance systems is to evaluate the effectiveness of worksite control programs.[11] However, there is little information addressing the effectiveness of government regulatory strategy in controlling work-related illness and injury, and there has certainly been controversy[14] in this regard. This study illustrates an overall decrease in the extent of lead poisoning over the last decade. However, on careful examination it is apparent that while the 1979 government order to reduce blood lead concentrations to below 3.38 µmol/L (70 µg/dl) was effective, the 1983 order to reduce blood leads to below 2.90 µmol/L (60 µg/dl) was less so. Thus the conclusion regarding the effectiveness of Manitoba's regulatory strategy is mixed.

Our findings show that when biological monitoring is the only criterion for compliance, utilization of administrative controls enables companies to comply with stricter regulations without decreasing overall lead exposure. The practice of administrative controls is problematic for several reasons. It results in subjecting more people to lead exposure, thereby failing to reduce overall lead exposure; it often causes employment disruption with its consequent socioeconomic consequences; it usually fails to reduce individual body burden of lead. The oscillations observed below the action level (Figure 2) do not represent lead exposure followed by lead excretion. Rather, due to man's relative inability to excrete lead, the downstrokes represent lead storage within the body. The end result of this process is chronic lead poisoning. This finding is supported by the clinical observations of the clinician authors (AY and MT) in which modest blood lead elevations in several long-term employees have been noted to be accompanied by marked increases in erythrocyte protoporphyrin concentrations.

In 1987 the minister responsible for occupational health in Manitoba issued a further order requiring "... a worker to be removed from the lead containing environment until his/her lead level returns to acceptable levels below 2.41 µmol/L (50 µg/dl). The worker may work in a job with minimal lead exposure (30 µg/M^3) considered as an 8 hour average ..." Moreover, the order stated that the exposure to the worker shall be "no greater than 50 µg/M^3 ... Only upon a detailed engineering assessment by a qualified engineer can consideration be given to permit exposure levels ... to exceed 50 µg/M^3." As most Canadian jurisdictions utilize the American Conference of Governmental Industrial Hygienist (ACGIH) level of 150 µg/M^3, this order was considered quite progressive by some and draconian by others. Regardless of the appropriateness of the lead-in-air concentration chosen, the data presented here demonstrate that the inclusion of an environmental target level was a needed addition. Nonetheless, biological monitoring must continue, with the data base described above serving an important role in monitoring the effectiveness of this new regulation.

In conclusion, while appreciation of lead as a subclinical toxin is essential, and a comprehensive blood lead surveillance system for high risk industries is crucial, unless biological monitoring is in conjunction with environment monitoring and measures to decrease exposure at the source, the overall goal of reducing occupational lead poisoning will not be achieved. ☐

Occupational Carpal Tunnel Syndrome in Washington State, 1984–1988

Gary M. Franklin, MD, MPH, Joanna Haug, MSc, Nicholas Heyer, PhD, Harvey Checkoway, PhD, and Neil Peck, MPA

ABSTRACT

Background: There are no published population-based studies of occupational carpal tunnel syndrome (OCTS) using a strict case definition. Most studies are either industry specific or present patient self-report of symptoms.

Methods: We conducted a population-based incidence study of OCTS using the Washington State Workers' Compensation database. Incident OCTS claims were identified with paid bills for physician reported ICD codes 354.0 and 354.1.

Results: There were 7,926 incident OCTS claims identified for the years 1984–1988, which yields an industry-wide incidence rate of 1.74 claims /1,000 FTEs. The mean age (37.4 years) and female/male ratio (1.2:1) in this population differ from those reported in nonoccupational carpal tunnel studies (mean age, 51 years; female/male ratio, 3:1). The female-specific OCTS incidence rate increased significantly during the study period. The highest industry specific OCTS rates were found in the food processing, carpentry, egg production, wood products, and logging industries.

Conclusion: Demographic differences and industry-specific rates consistent with workplace exposures suggest that OCTS is distinct from CTS occurring in nonoccupational settings. Workers' compensation data proved useful in identifying high risk industries. (*Am J Public Health.* 1991;81:741–746)

Introduction

Occupational carpal tunnel syndrome (OCTS) is a major cause of lost work days and workers' compensation costs in the United States. A recent Centers for Disease Control report, based on physician reporting, estimated that 47 percent of carpal tunnel cases are work-related.[1] Industry-specific prevalence rates of OCTS have been reported to be as high as 15 percent.[2] Most such reports reflect prevalence rates in individual plants or small populations of workers.

Population-based data on the incidence of OCTS has been difficult to generate. The principal problem appears to be that OCTS does not have a unique code in the US Department of Labor Z–16.2 coding system. All wrist disorders are aggregated, and specifically diagnosed cases of OCTS cannot be identified routinely. A recent report using Wisconsin workers' compensation data could identify only "potential" OCTS cases.[3]

Washington State Department of Labor and Industries' claims and medical bill payment information systems were utilized to generate age-, sex- and industry-specific OCTS rates for the years 1984–88. In the context of this study, the validity of using such an administrative data base in performing epidemiologic research was investigated.

Methods

Workers' Compensation System

The Washington State Department of Labor and Industries (L&I) is the sole regulator of workers' compensation coverage in Washington State covering approximately 1.3 million full-time workers in 1988. Coverage for roughly one-third of these workers is through self-insurance administered company programs, and the other two-thirds of workers are covered by the Washington State Fund.

Claims Management Data Base

The L&I claims management data base consists of two major data processing systems. The Medical Information and Payment System receives all billing information generated by provider medical bills. This system records such relevant items as dates of service, all associated procedure (CPT) codes, and physician diagnosis by International Classification of Disease (ICD)[4] code for each provider visit.

The Labor and Industries Industrial Insurance System contains all data necessary for administration of claims. Recorded data include age, sex, claim ID, claimant ID, social security number, nature of injury (Z16.2) codes, time loss, and medical aid paid-to-date. In addition, industry type is coded using the Washington Industrial Classification (WIC) system.

B. *Objective findings* consistent with CTS:
Either
  1) *Positive physical examination* findings −(+) Tinel's or Phalen's or decreased or absent sensation to pin prick in median nerve distribution of the hand; or
  2) *Nerve conduction findings* indicative of median nerve dysfunction across the carpal tunnel; and

C. Evidence of work-relatedness—a history of a job involving one or more of the following activities *prior to* development of CTS symptoms:
  1) *Frequent, repetitive* use of the hand or wrist,
  2) Regular tasks requiring the generation of *high force* by the hand,
  3) Regular or sustained tasks requiring *awkward hand positions,*
  4) Regular use of *vibrating hand tools,*
  5) Frequent or prolonged *pressure over the wrist or base of the palm.*

Incident OCTS Claim Definition

A data extract was generated of all medical bill line items with an ICD code of 354.0 (carpal tunnel syndrome) or 354.1 (median nerve neuritis) from both the claims and medical bill payment systems. The data set included both compensable (time loss) and non-compensable claims for which medical bills were paid between January 1, 1984 and December 31, 1988. Self-insured claims were excluded from both the numerator and denominator in subsequent analyses due to incomplete data.

An incident claim was defined as the first appearance of a paid bill for a claimant with a physician ICD diagnosis of 354.0 or 354.1 between 1984–88. An algorithm was developed to identify unique claimants by claimant ID and social security numbers. This process ensured the removal of multiple claims for the same condition or conditions recurring at a later date, and eliminated problems of missing claimant identifiers for archived claims.

Denominators

OCTS incidence rates by year and industry were estimated directly using worker hours reported to L&I. Worker hours were converted to full time equivalent workers (FTEs) by FTEs = total hours reported/2000.

Age- and sex-specific denominators were not available from worker hours reported to L&I and were estimated by using other available data. Census data for Washington State (1980) were used to estimate an age/sex distribution for the employed population. The Office of Financial Management state and county projected population figures for 1980–91 were used to determine percent changes in the age/sex-specific strata between 1980 and the years of interest.

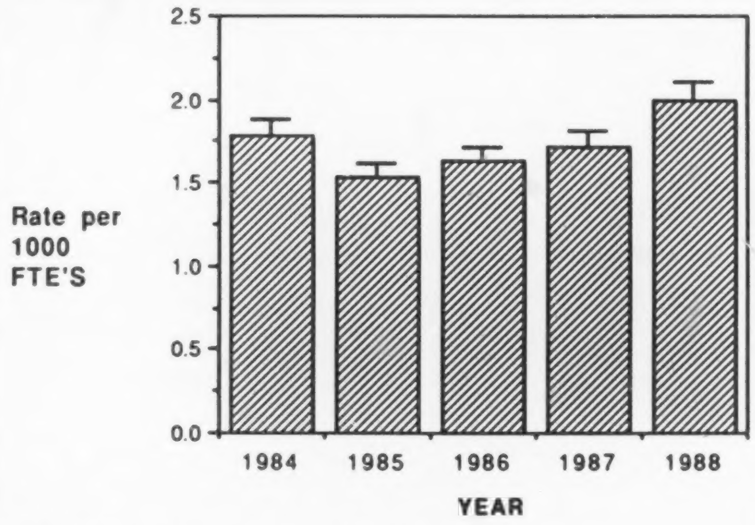

FIGURE 1—Carpal Tunnel Syndrome Incidence Rates 1984–88

Industry-Specific OCTS Rates

Worker hours reported to L&I represent hours of exposure by Washington Industrial Classification (WIC). An industrial classification is a grouping of industries that share similar workplace exposures. Currently there are 975 industrial classifications. OCTS rates are presented using WIC classifications as a surrogate for industry type. In order to eliminate unstable rates, only those classifications with a minimum of 25 OCTS cases over the five-year study period were included in the study.

Misclassification Studies

Two separate sub-studies were performed in an attempt to define potential misclassification: 1) a validation study using the medical records for a random sample of 245 incident claims during the period 1984–88 to estimate (a) the proportion of claims with a documented physician diagnosis, and (b) the proportion of claims that fit the clinical criteria for case definition according to National Institute for Occupational Safety and Health (NIOSH) standards (Table 1)[1], and 2) a review of ICD coding errors associated with a separate sample of L&I claimants who received carpal tunnel surgery between 1984–87.

Statistical Methods

Incidence rates by age, sex, year, and industry are expressed as numbers of OCTS claims/1,000 FTEs. A statistical comparison of rates for male/female differences and test for trend over time were done using formulas reflecting a Poisson distribution.[5,6] Each industry-specific rate was compared to the industry-wide rate, and a crude incident rate ratio with a 95 percent confidence interval was developed.[6]

Results

OCTS Incidence by Age, Sex, and Year

Figure 1 shows that the incidence rate for OCTS claims increased from 1.78/1,000 FTEs in 1984 to 2.00/1,000 FTEs in

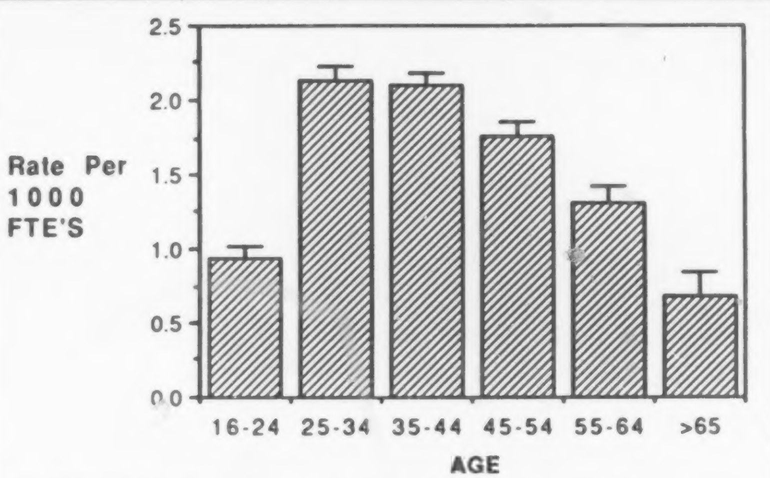

FIGURE 2—Carpal Tunnel Syndrome Incidence Rates by Age 1984–88

1988 (1,533 claims in 1984; 1,320 claims in 1985; 1,475 claims in 1986; 1,642 claims in 1987; and 1,956 claims in 1988). The trend of increase is statistically significant ($p < .01$).

The OCTS incidence rate peaked in the 25–44 age group (mean age 37.4 years) (Figure 2). The overall incidence rate for females (1.96/1,000 FTEs) was significantly greater than that for males (1.58/1,000 FTEs, $p < 0.001$), and this difference has increased over time (Figure 3). The female OCTS incidence rate increased significantly between 1984–88 ($p < 0.005$), while the male incidence rate remained stable with no statistically significant trend.

Industry-Specific OCTS Incidence Rates

For the period 1984–88, the industry-wide OCTS incidence rate was 1.74 claims/1,000 FTEs. The top 20 industries are presented sorted by rate (Table 2) and by total number of incident claims (Table 3). The highest OCTS rate of 25.7 claims/1,000 FTEs for oyster, crab, and clam packing was approximately 15-fold higher than the industry-wide rate (1.74 claims/1,000 FTEs).

Misclassification

OCTS Case-Definition Study—In order to validate the methodology used to identify OCTS claims, medical records for a random sample of 245 incident OCTS claims were reviewed. Two hundred and one (201) out of 245 claims (82 percent) did have a physician diagnosis of OCTS documented in the medical records. The proportion of incident claims without a clear diagnosis of OCTS was consistent across age, sex, and year; no significant differences in proportions were seen within these categories. A high correlation was found between physician diagnosis of OCTS and the criteria set out by NIOSH for case definition. Of the 201 cases with a physician diagnosis in the medical records, 186 (93 percent) met NIOSH standards for OCTS.

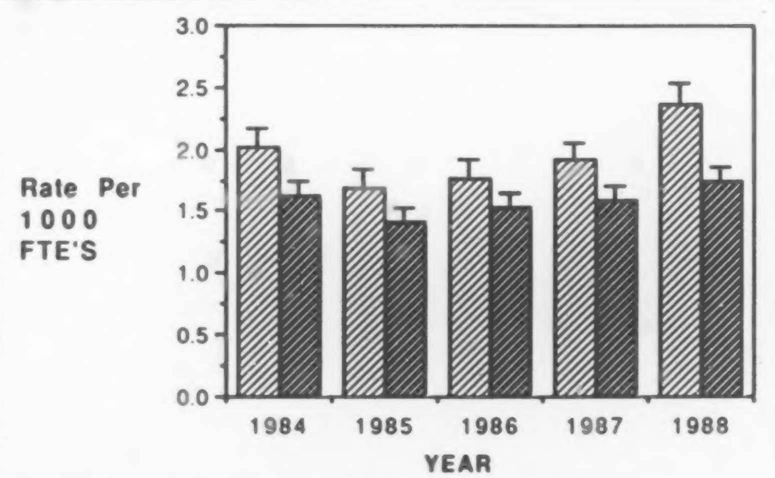

FIGURE 3—Carpal Tunnel Syndrome Incidence Rates by Sex 1984–88

An attempt was made to reduce the potential misclassification due to "false" OCTS claims (missing a clear physician diagnosis) by testing more restrictive incident claim definitions (Table 4). The baseline inclusion criteria of at least one visit with ICD codes 354.0 or 354.1 resulted in a "false" claims rate of 18 percent (44/245) in the validation study. Minimally increasing the inclusion criteria to: a) more than one visit with ICD codes 354.0 or 354.1, or b) subsequent carpal tunnel surgery, would exclude 77 percent (34/44) of the "false" OCTS claims. However, 32 percent (64/201) of the true claims (with physician diagnosis) would also be excluded.

Diagnostic Coding Error Study—In order to determine how much misclassification by diagnosis exists in the data base, an extract was made of all medical bills with a CPT procedure code of 64721 (carpal tunnel decompression surgery) for the time period 1984–87. There were 2,507 unique carpal tunnel surgery claims with 212 associated ICD codes. A classification system (Table 5) was developed to assign the various diagnoses as: 1) CTS with ICD codes 354.0 or 354.1; 2) CTS of traumatic origin; or 3) all other ICD codes. This misclassification study is based on the assumption that all surgeries were indeed cases of CTS. If data were extracted from the system based entirely upon ICD codes 354.0 or 354.1, only 71.6 percent (1,793/2,507) of CTS claims would be captured. Only 3.4 percent (86/2,507) of claims that had received carpal tunnel surgery had diagnosis codes suggesting CTS of traumatic origin. Other diagnosis and data entry errors comprised 25 percent (628/2,421) of CTS surgery claims.

TABLE 2—Rates and Cases of Carpal Tunnel Syndrome by Washington Industrial Classification (WIC), 1984–88 (sorted by rate)

Industrial Class Description	Cases N	Rate/FTE 1000	Rate Ratio	95% Confidence Interval
Oyster, crab, clam packing	50	25.7	14.8	(11.2, 19.5)
Meat, poultry dealers	132	23.9	13.8	(11.6, 16.4)
Packing house	55	18.5	10.6	(8.1, 13.8)
